BOX 9-2
COMMON CAUSES OF ENLARGED EXTRAOCULAR MUSCLES AND SUBPERIOSTEAL LESIONS

Enlarged Extraocular Muscle

Graves' myositis
Inflammatory myositis, including cysticercosis
Granulomatous myositis (less common)—sarcoidosis
Pseudotumor (myositic type)
Lymphoma
Vascular lesions (hemangioma, arteriovenous malformation)
Aromegaly
Pseudorheumatoid nodule
Metastasis (breast, lung)

Orbital Subperiosteal Lesions

Subperiosteal cellulitis
Subperiosteal abscess
Infiltration of neoplastic lesions of paranasal sinuses
Infiltration of meningiomas (en plaque meningiomas)
Lymphomas
Leukemia
Plasmacytomas
Lacrimal gland tumors
Dermoid and epidermoid
Hematoma and hematic cyst
Cholesterol granuloma
Fibrous histiocytoma
Primary osseous or cartilaginous tumors
Metastasis (neuroblastoma)

BOX 9-3
EXTRACONAL PERIPHERAL ORBITAL LESIONS

More Common

Capillary hemangiomas
Cholesterol granulomas
Dermoids and epidermoids
Lacrimal gland lesions
- Inflammation
- Lymphoma
- Pseudotumor
- Sarcoidosis

Epithelial tumors
Lymphangiomas
Peripheral nerve tumors
Plasmacytomas
Rhabdomyosarcomas
Sarcoidosis

Less Common

Amyloidosis
Fibrous histiocytoma
Hemangiosarcoma
Hemangiopericytoma
Hematic cyst
Lipoma
Orbital encephalocele
Wegener's granulomatosis

BOX 9-4
DIFFERENTIAL DIAGNOSIS OF METASTATIC ORBITAL CALCIFICATION

Congenital
- Fanconi's syndrome (proximal renal tubular dysfunction)
- Milk-alkali syndrome
- Renal tubular acidosis

Endocrine
- Hyperparathyroidism, primary or secondary
- Hypoparathyroidism
- Pseudohypoparathyroidism

Idiopathic—sarcoidosis
Infectious
- Cytomegalovirus
- Leprosy
- Osteomyelitis
- Syphilis
- Toxoplasmosis
- Tuberculosis

Toxic
- Excessive ingestion of calcium phosphate or alkali
- Vitamin D intoxication

Traumatic—immobilization
Neoplastic
- Bronchogenic carcinoma
- Metastatic involvement of bone
- Multiple myeloma
- Parathyroid adenoma
- Parathyroid carcinoma

walls of the bony orbits measured at the juncture of the crista lacrimalis posterior with the frontolacrimal suture.[31] Currarino and Silverman, in their studies of arhinencephaly and trigonocephaly, measured the BID between the medial walls at what was described to be the junction between each medial angular process of the frontal bone with the maxillary and lacrimal bones.[28]

To provide a statistically more reliable standard, Gerald and Silverman repeated the original work of Currarino and Silverman, using the same technical factors, and studied 100 patients at each year of age from birth to 12 years.[28, 29] Hansman, using radiographs of the skull and paranasal sinuses in a large group of healthy subjects, presented measurements of the BID and the thickness of the skull.[32] According to him, from infancy to adulthood, the BID for girls is consistently narrower than for boys. Starting at 1 year 6 months, there is a gradual increase in the size of the BID for both sexes. At about 13 years of age, girls' growth begins to level off. Since boys' growth continues to increase to the age of about 21 years, the measurements in girls fall more markedly below those of boys as growth is completed. The average adult measurement in women is 25 mm and in men is 28 mm.[32]

CT of the orbit provides, along with other information, an opportunity to evaluate the distance between the orbits and, if necessary, any other linear and angular measurements. On

From Froula PD et al. The differential diagnosis of orbital calcifications, as detected on computed tomographic scans. Mayo Clin Proc 1993;68:256-257.

CT, the lacrimal bones and orbital plates of the ethmoid (lamina papyracea) are seen as a thin line of bone, and the BID can be measured at any desired point.[19] From the CT studies of 400 adults (200 men aged 18 to 82, average age 52; 200 women aged 17 to 88, average age 54), the BID was measured between the medial walls of the orbits, along with certain other linear and angular measurements; these data are given in Table 9-1. These data were collected from patients with normal orbits who were studied because of a suspected diagnosis of brain infarction, hearing loss, or brain tumor. None of these patients had any underlying craniofacial anomaly or congenital malformation. The patients were Caucasian, except for a few who were Asian. In this study, data were collected only from nonrotated axial sections in the plane of the optic nerve (Fig. 9-28). On similar CT sections through the orbits, there are two configurations of the medial orbital walls. The first is a parallel separation of the medial orbital walls, and the second is a fusiform or lateral spread of the ethmoidal air cells, with the widest separation of the orbital walls occurring posterior to the posterior pole of the globe.[19] The distance between the medial walls of the bony orbits at various points, and other linear and angular measurements, are illustrated in Figure 9-28A,B. Several reference points have been used. The anterior pole (*A*) is applied to the central point of the anterior curvature of the eyeball, and the posterior pole (*P*) is the central point of its posterior curvature. A line joining the two poles forms the optic axis (*AP*), and the primary axes of the two globes are nearly parallel. The cranial opening of the optic canal is well demonstrated in Figure 9-28A. The optic canal lies between the root of the lesser sphenoid wing and the body of the sphenoid bone (Fig. 9-28A and 9-29). The anterior root is broad and flat and is continuous with the planum sphenoidale (Figs. 9-26 and 9-28A). The posterior root is shorter and thicker (optic strut), and is connected to the body of the sphenoid opposite the posterior border of the sulcus chiasmatis.[19]

As seen in Table 9-1, the normal BID, measured at the posterior border of the frontal processes of the maxilla on nonrotated CT scans in the plane of the optic nerve, ranges from 2.29 to 3.21 cm (average, 2.67 cm) in men and 2.29 to 3.20 cm (average, 2.56 cm) in women. The widest interorbital distance lies behind the posterior poles of the globes. This ranges from 3.16 to 4.10 cm (average, 3.37 cm) in men and 2.93 to 3.67 cm (average, 3.20 cm) in women. A line joining the lateral orbital margins in the axial plane (line DD in Table 9-1 (Figs. 9-26 and 9-28B) normally intersects the globe near its midportion, with at least one third of the globe posterior to this line.

PATHOLOGY

Hypertelorism, Hypotelorism, Exophthalmos, and Exorbitism

The terminology used to describe abnormalities of the orbit is complicated and may be confusing[33] to those unfamiliar with it. It will therefore be briefly reviewed. *Hypertelorism* is literally translated from Greek as ''increased distance'' (*hyper* meaning ''over'' and *tele* meaning

''distant''). Orbital hypertelorism describes the anatomic situation in which the medial walls of the orbits are farther apart than normal.[33-35]

Patients with orbital hypertelorism almost always have eyes that are spaced more widely apart than normal. Telecanthus is a condition that may clinically mimic orbital hypertelorism. In telecanthus the distance between the apices of the medial canthal ligaments is increased, and the eyes are spaced more widely apart than normal. However, the BID is not increased; these patients do not have orbital hypertelorism. They do have medial canthal hypertelorism. Telecanthus may be congenital or acquired; when acquired, it is often a consequence of trauma.[33]

Orbital *hypotelorism* refers to a decrease in the BID. Patients with this condition may appear clinically to have either narrowly spaced or normally spaced eyes; surprisingly, they may even appear to have widely spaced eyes. For example, patients with Down's syndrome and trisomy 13 syndrome were classically described as having hypertelorism on the basis of clinical evaluation. However, in fact, these patients have orbital hypotelorism.[33, 35]

Exophthalmos describes abnormal prominence of the globe, and proptosis emphasizes abnormal protrusion of the globe. *Exophthalmos* and *proptosis*, however, commonly are used as synonyms. *Exorbitism*, on the other hand, refers to a decrease in the volume of the orbit. The orbital contents are greater in volume than the orbital capacity and generally protrude anteriorly (proptosis), causing the globe to be unusually prominent (exophthalmos).

Congenital and Developmental Abnormalities

There are many hereditary and sporadic abnormalities that involve the orbits, globe, adjacent orbital tissues, and other craniofacial and skeletal structures. The embryology of the eyes and orbits is presented in Chapter 8 and earlier in this chapter. The embryology of the midface is presented in Chapter 1. The study of these congenital and developmental conditions is complicated by the variety of names used for the same syndrome and by the overlapping criteria used to establish the diagnosis of a syndrome.[36] To list all of the congenital malformations or syndromes is beyond the scope of this chapter. Many excellent books have detailed descriptions of these disorders.[34-39] The eyes are often involved in craniofacial malformations, including orbital clefts and orbital hypotelorism and hypertelorism. CT and MR imaging have proven to be very useful in the preoperative evaluation of such patients, and imaging may show an encephalocele or a porencephalic cyst as an additional feature of the malformation.[19] The surgical treatment of hypertelorism involves translocation of the globes toward the midline by lateral wall osteotomy at a point posterior to the equator of the eye.[19]

Anatomic and Developmental Considerations

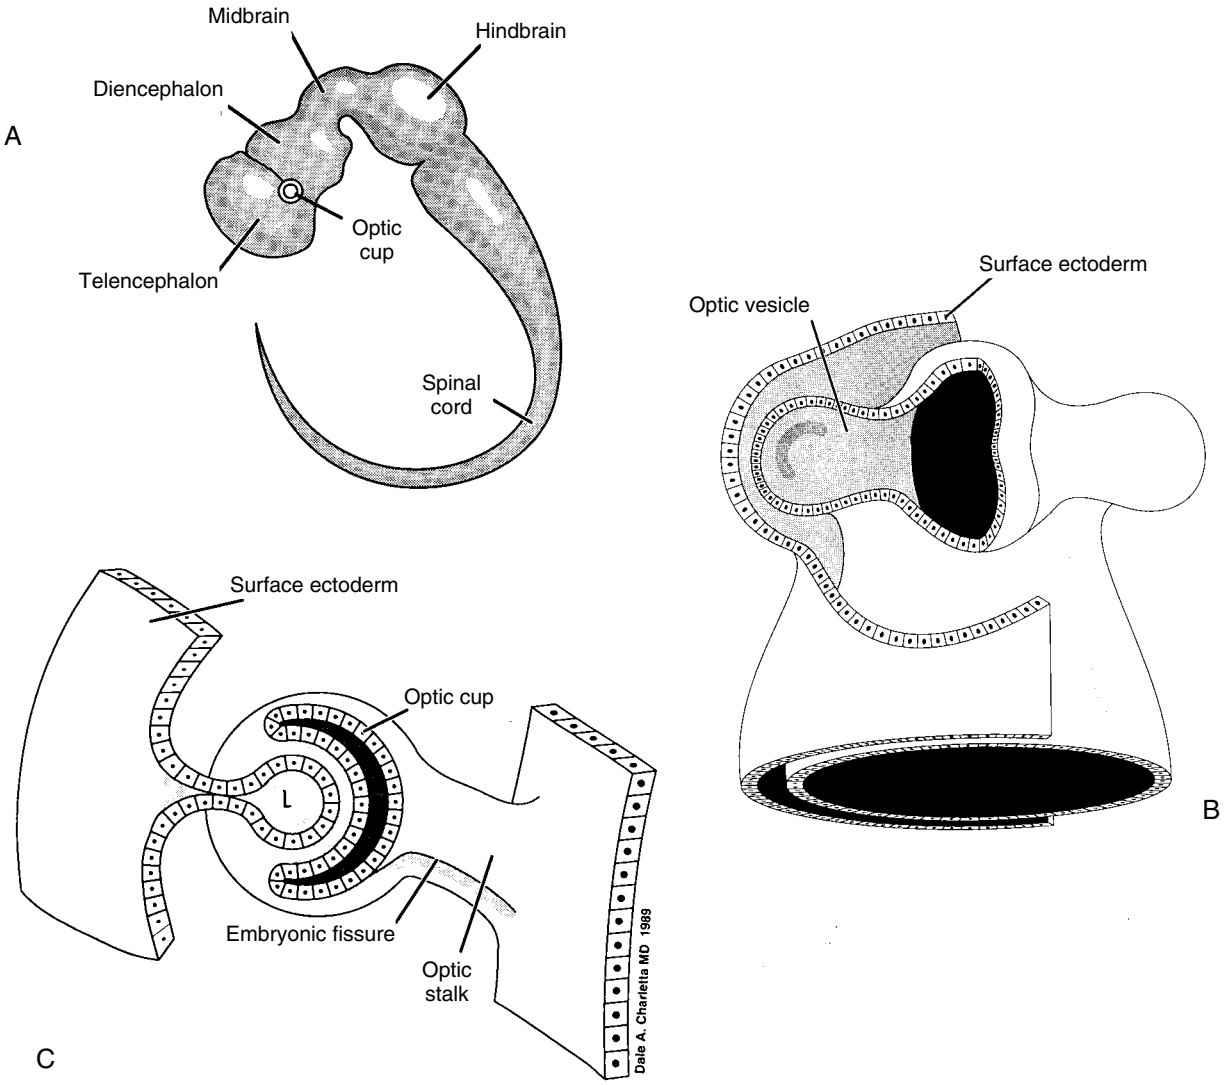
Congenital abnormalities of the orbit and eyes result from faulty development of the embryo and fetus, and the eighth week of gestation is the last week of true embryonic development.[36, 40-46] By the third week of gestation, the optic pits appear, one on either side of the forebrain. Disturbance of the prosencephalic organizing center (prechordal mesoblast) can cause cyclopia, synophthalmia, or arhinencephaly. Anophthalmia occurs as a result of failure of the neuroectoderm of the optic pit to develop from the anterior portion of the neural plate. A variety of ocular and systemic abnormalities may be seen with an optic nerve coloboma. These conditions have been described in Chapter 8. Craniosynostosis is due to abnormal development of the blastemic stage of the skull bone, including the basicranium. Mandibulofacial dysostosis and otocephaly probably are due to inhibition of mesodermal differentiation of the facial structures derived from the first branchial (visceral) arch. These conditions are discussed in Chapter 1.[36]

Under normal conditions, the eye directs orbital growth.

Copyright © 2003, Mosby, Inc. All rights reserved.

During the first year of life, the eye practically doubles in volume and attains more than 50% of its adult volume.[47] By the end of the third year, 75% of the adult volume is achieved (similar to neural growth).[47] The shape of the orbital cranial junction is also influenced by the development of the brain and skull.[47] When the brain is underdeveloped but the eye is normal, the orbital plate of the frontal bone is usually elevated into the anterior fossa of the skull.[19] In microcephaly the orbits are usually circular and the roofs are highly arched.[48] When the eye is underdeveloped but the brain is normal, the orbital plate of the frontal bone appears hypoplastic and the vertical or cranial part is usually normal (Fig. 9-30). Enucleation of the globe in infancy and early childhood, if untreated with a prosthesis, leads to arrested development of the orbit, resulting in a small orbit.[36]

In coronal suture synostosis, the orbit on the side of the fusion is elongated superiorly and laterally, imparting a harlequin appearance (Fig. 9-31). Correction of the cranial deformity can lead to spontaneous correction of the orbital deformity in some instances.[49, 50] In mandibulofacial dysostosis, the orbits may be defective inferolaterally because of malar bone hypoplasia. In cases of severe malar hypoplasia, the lateral wall of the orbit is formed by the greater wing of



VIEW IMAGE

FIGURE 9-30 **A**, A 5-mm developing human embryo (4 weeks of gestation). By 3 weeks of gestation two indentations appear, one on either side of the neural groove. These are optic pits, which deepen to form the optic vesicles, one on either side of the forebrain. The optic vesicles give rise to an optic stalk and optic cup on either side. **B**, Development of the posterior ocular structures. In the 4 mm embryo, lateral diverticula on either side of the forebrain have given rise to two optic vesicles. The distal portions of the optic vesicles expand, and the proximal portions become the tubular optic stalks. **C**, At the 5 mm stage, the external surface of each optic vesicle invaginates to form the optic cup. The inner wall of the optic cup (formerly the outer wall of the optic vesicle) gives rise to the retina, and the outer wall of the cup becomes the retinal pigment epithelium. The optic vesicle is covered by a layer of surface ectoderm, which forms the lens (*L*). Note the embryonic fissure, through which mesenchyme extends into the optic stalk and cup. Failure of the embryonic fissure to close causes typical ocular colobomas. (From Mafee MF et al. CT of optic nerve colobomas, morning glory anomaly, and colobomatous cyst. Radiol Clin North Am 1987;25:693.)

VIEW IMAGE

FIGURE 9-31 **A**, Microphthalmia. Posteroanterior view of the skull. The lesser wing of the sphenoid (*2*) and the left maxillary sinus are hypoplastic; superior orbital fissures are asymmetric (*1*). Note the difference between the oblique lines (*horizontal arrows*), which represent cortices of the temporal surface of the greater wings of the sphenoid bone. Notice the hypoplasia of the roof of the left orbit (*vertical arrows*). **B**, Microphthalmia. Four-year-old boy born without a nose and with left microphthalmos and apparent hypertelorism. The left globe is smaller than the right. Increased soft tissue between the medial wall or orbit and the globe anteriorly has the clinical appearance of hypertelorism. In fact, the interorbital bony distance is normal. (From Mafee MF et al. CT in the evaluation of the orbit and the bony interorbital distance. AJNR 1986;7:265.)

the sphenoid and the zygomatic process of the frontal bone (also see Chapter 1).

Bony Abnormalities

Minor degrees of facial and orbital asymmetry are the most common causes of pseudoproptosis.[4] For the most part, these patients have minor degrees of asymmetry involving all of the hemifacial structures.[3] However, in a few instances, the asymmetry may be related to maxillary hypoplasia resulting in a relatively retroplaced orbit on the affected side. In many cases, familial asymmetry may be evident when the siblings or parents are examined. These minor developmental abnormalities of the orbit are considered anatomic variations. Anomalies of ossification may result in accessory sutures and supernumerary ossicles in the orbital walls.[36] On rare occasions, congenital absence of bone in the frontal, maxillary, and orbital regions may result in deformity of the bony orbit. Asymmetric enlargement of one bony orbit may be due to eccentrically located lesions such as neurofibroma, hemangioma, lymphangioma, dermoid, and other slow-growing processes. A small orbit is seen in anophthalmia, microphthalmia, and postenucleation of the globe in infancy, if not followed by prompt prosthetic treatment.

Bony Orbit in Craniofacial Dysostosis

Craniofacial dysostosis and developmental anomalies may result in profound orbital abnormalities. Orbital malformations in craniofacial dysostosis result chiefly from coronal synostosis. Premature closure of one or more cranial sutures, termed *craniosynostosis* or *craniostenosis*, is the common denominator of many patients with craniofacial anomaly.[51–58]

Primary Congenital Isolated Craniosynostosis

Any cranial suture may undergo premature closure, but several patterns are recognizable more commonly than others.[50] The incidence of congenital suture synostosis reported by Harwood-Nash,[51] derived from a composite of his experience and from two large series reported by Anderson and Geiger[52] and Shillito and Matson,[53] is as follows: sagittal, 56%; single coronal, 11%; bilateral coronal, 11%; metopic suture, 7%; lambdoid, 1%; and three or more sutures, 14%. Depending on the suture that is prematurely closed, the skull and orbit, including the interorbital distance, have a characteristic shape. These can be grouped as follows: (1) metopic; trigonocephaly (triangular head); hypotelorism is a constant feature of the trigonocephaly;[48] (2) sagittal, scaphocephaly (dolichocephaly), in which the anteroposterior diameter of the bony orbit is usually increased and the vertical and transverse diameters of the bony orbit are usually decreased; (3) unilateral coronal or lambdoid; plagiocephaly; in this condition, if the coronal suture is involved, there is characteristic deformity of the bony orbit, which will be discussed later; (4) bilateral coronal or lambdoid, resulting in brachycephaly; (5) coronal and sagittal; oxycephaly or acrocephaly (turricephaly); and (6) coronal, lambdoid, and sagittal;

Copyright © 2003, Mosby, Inc. All rights reserved.

cloverleaf skull (kleeblattschädel). Primary craniosynostosis may be associated with congenital syndromes. These conditions include the following: Crouzon's disease (craniofacial dysostosis), Apert's disease (acrocephalosyndactyly, type I), Saethre-Chotzen syndrome (acrocephalosyndactyly, type II), Carpenter's syndrome (acrocephalopolysyndactyly), chondrodystrophia calcificans congenita (Conradi's syndrome, or punctate epiphyseal dysplasia), Brachmann-de Lange syndrome, Laurence-Moon-Biedl-Bardet syndrome, Treacher Collins syndrome (mandibulofacial dysostosis), and craniotelencephalic dysplasia.[39, 48, 50]

Orbit in Plagiocephaly

Plagiocephaly is due to unilateral closure of one of the paired sutures of the skull, frequently the coronal or lambdoid but rarely the temporosquamous sutures. Each produces a characteristic deformity of the skull. In practice, most of the time, plagiocephaly is seen in patients with hemicoronal premature synostosis, in which there is an ipsilateral elevation of the lesser wing of the sphenoid associated with upward extension of the superior lateral portion of the orbit, imparting a harlequin appearance to the orbit (Fig. 9-32A).[50] The flattening of the ipsilateral frontal bone is also characteristic of premature coronal synostosis (Fig. 9-32B). The volume of the anterior cranial fossa on the side of fusion is decreased. The greater wing of the sphenoid is expanded, displaced forward and downward, and forms a relatively large middle cranial fossa (Fig. 9-32B,C). This occurs in addition to upward elevation of the roof of the orbit, which produces a shallow orbit. The ethmoidal plate (roof of the ethmoidal sinus) also is elevated on the side of fusion (Fig. 9-32A). The nasal septum, crista galli, and ethmoidal complex are tilted to the side of fusion (Fig. 9-32A).

Premature fusion of both coronal sutures may occur with or without any other associated abnormality. This may result in marked shortening of the anterior cranial fossa and orbital depth, and the brain impressions become more prominent on the inner table of the frontal bone (Fig. 9-33). Both a harlequin appearance of the orbit and the bony changes of the unilateral coronal synostosis are duplicated in this bilateral form of premature fusion (Fig. 9-33). Lombardi noted a connection between sagittal or lambdoid synostosis, or both, in half of the reported cases of coronal suture synostosis.[55]

Orbit in Crouzon's and Apert's Diseases

Crouzon's disease, also known as *craniofacial dysostosis*, is an autosomal dominant disorder with considerable variability in expression.[50] Apert's disease, also known as *acrocephalosyndactyly type I*, is transmitted as an autosomal dominant disorder. The cranial and facial characteristics of Crouzon's disease are somewhat similar to those of Apert's syndrome, including brachycephaly, hypertelorism, bilateral exophthalmos, parrot-beaked nose, maxillary hypoplasia, relative prognathism, and a drooping lower lip that produces a half-open mouth. Bilateral exophthalmos is essentially a consequence of exorbitism, which in turn is a consequence of several factors that combine to produce a decrease in orbital volume. On the basis of the skull shape alone, Crouzon's and Apert's diseases cannot be distinguished.[50]

In any large series of patients with Crouzon's disease, there is no regular pattern of calvarial deformity. Oxycephaly, brachycephaly, scaphocephaly, and trigonocephaly may be present. In fact, there is too much heterogeneity to allow for a simplistic description. Generally, in Crouzon's disease, brachycephaly, or oxycephaly, is most often observed. Apert's disease is characterized by irregular craniostenosis with an acrobrachycephalic skull and syndactyly of the hands and feet. Associated skeletal abnormalities such as ankylosis of the elbow, hip, and shoulder, as well as malformations of the cardiovascular, gastrointestinal, and genitourinary systems, may be present.

The orbital malformation in Crouzon's and Apert's diseases is due mainly to premature coronal synostosis. A striking harlequin appearance of the orbits is seen that results from elevation of the roof and lateral walls of the orbits (Fig. 9-34). The supraorbital rim is recessed, and the infraorbital rim is hypoplastic. The orbital depth is markedly reduced as the result of verticalization of the roof (upward tilt of the lesser wing and orbital plate of the frontal bone). Displacement of the greater wing of the sphenoid into a more coronal orientation, which is referred to as *frontalization* of the greater wing of the sphenoid, and ballooning of the ethmoid are other factors contributing to exotropia. Hypoplasia of the maxilla and the intermaxillary component contributes in part to the exophthalmos and relative prognathism (Figs. 9-34 and 9-35). Hypoplasia of the maxilla causes recession of the infraorbital rim and foreshortening of the orbital floor.[50] The optic canal in Crouzon's and Apert's diseases is usually narrow. This may lead to optic atrophy.[3] The distance between the intracranial openings of the optic canals is usually normal, and this finding forms the basis for surgical procedures designed to correct orbital hypertelorism by moving the bony orbits closer together without damaging the optic or oculomotor nerves.[50] Of particular importance to the surgeon contemplating surgical correction of orbital hypertelorism are the orientation and degree of foreshortening of the lateral wall of the orbit. The type of lateral wall osteotomy performed (sagittal split or total mobilization) often depends on these anatomic factors.[33, 34] Patients with craniosynostosis syndromes may have marked extraocular muscle anomalies ranging from an apparent absence of ocular muscles to abnormally inserted muscles or very small extraocular muscles (Figs. 9-34 to 9-36).

Saethre-Chotzen Syndrome (Acrocephalosyndactyly Type II)

Saethre-Chotzen syndrome was described by Saethre in 1931 and in 1932 by Chotzen.[50, 55-57] The first family with this disease to be reported in the United States was described in 1970 by Bartsocas et al.[58] Saethre-Chotzen syndrome is characterized by synostotic malformation of multiple sutures, facial asymmetry, mild midface hypoplasia, ptosis of the eyelids, an antimongoloid slant of the palpebral fissures, a beaked nose, a low-set frontal hairline, variable brachycephaly, and variable cutaneous syndactyly, particularly of the second and third fingers. Other associated abnormalities

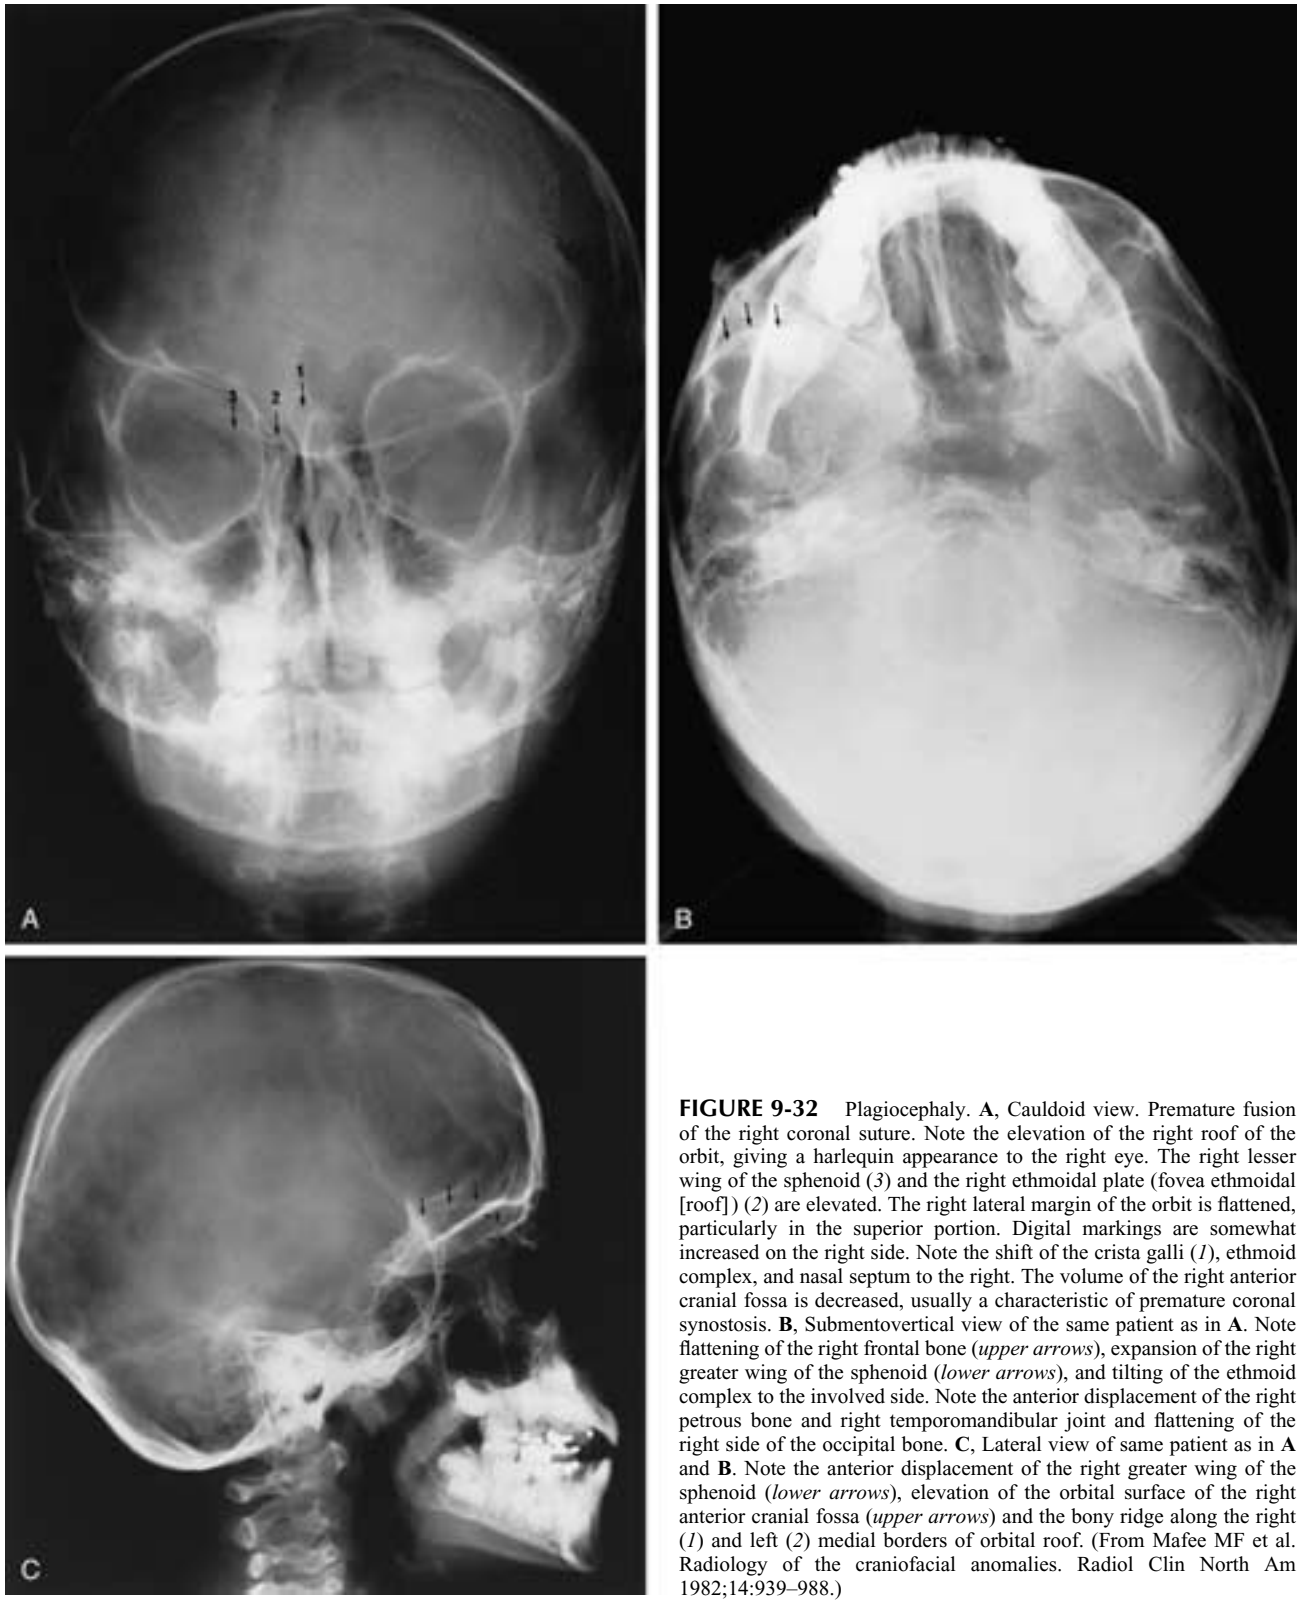

FIGURE 9-32 Plagiocephaly. **A**, Cauldoid view. Premature fusion of the right coronal suture. Note the elevation of the right roof of the orbit, giving a harlequin appearance to the right eye. The right lesser wing of the sphenoid (*3*) and the right ethmoidal plate (fovea ethmoidal [roof]) (*2*) are elevated. The right lateral margin of the orbit is flattened, particularly in the superior portion. Digital markings are somewhat increased on the right side. Note the shift of the crista galli (*1*), ethmoid complex, and nasal septum to the right. The volume of the right anterior cranial fossa is decreased, usually a characteristic of premature coronal synostosis. **B**, Submentovertical view of the same patient as in **A**. Note flattening of the right frontal bone (*upper arrows*), expansion of the right greater wing of the sphenoid (*lower arrows*), and tilting of the ethmoid complex to the involved side. Note the anterior displacement of the right petrous bone and right temporomandibular joint and flattening of the right side of the occipital bone. **C**, Lateral view of same patient as in **A** and **B**. Note the anterior displacement of the right greater wing of the sphenoid (*lower arrows*), elevation of the orbital surface of the right anterior cranial fossa (*upper arrows*) and the bony ridge along the right (*1*) and left (*2*) medial borders of orbital roof. (From Mafee MF et al. Radiology of the craniofacial anomalies. Radiol Clin North Am 1982;14:939–988.)

Note elevation of the lesser wings of the sphenoid (*vertical arrows*) and harlequin appearance of both orbits. Note the stretched and laterally placed oblique lines (*horizontal arrows*) and flattening of the lateral wall of the orbits with a recessed lateral orbital rim. **B**, Lateral skull view of the same patient as in **A** shows absence of sutural lines, increased digital markings, downward and forward displacement of the greater wings of the sphenoid bone (*large black arrows*), elevation of the roof of the orbits (*small black arrows*), and low position of the planum sphenoidale (*white arrows*).

include a high-arched palate, cleft palate, and deformity of the external ear. The orbital abnormalities in these patients are similar to those in Crouzon's and Apert's diseases.

Neurofibromatosis

The classic description of neurofibromatosis was published by Friedrich Daniel von Recklinghausen in 1882. Clinical criteria for diagnosing neurofibromatosis include (1) six or more café-au-lait spots, each greater than 1.5 cm in diameter; (2) axillary or other intertriginous freckles; (3) cutaneous neurofibromas; and (4) one or more unequivocally affected parents or siblings.[59] The disease itself is characterized by abnormalities of both ectodermal and mesodermal origin. It is transmitted as an autosomal dominant disorder of variable penetrance.[33] The incidence of neurofibromatosis is approximately 1 in 3000 live births.[60] About 50% of these patients have a positive family history of the disease, and the other 50% are the result of a spontaneous mutation; the mutation rate is about 10:4.[61] The incidence of central nervous system tumors, including acoustic neuromas, gliomas, meningiomas, and ependymomas, is six times that of the general population.[62] Often multiple central nervous system tumors are present. Although 25% to 35% of neurofibromas occur in the head and neck region, orbital abnormalities are relatively uncommon.[60] Orbital abnormalities are often associated with exophthalmos, which may be pulsatile and generally can be classified into one of four categories: (1) orbital neoplasms; (2) plexiform neurofibromatosis; (3) orbital osseous dysplasia (Fig. 9-37); and (4) congenital glaucoma.[60] The most common orbital neoplasm seen in association with neurofibromatosis is optic glioma (Fig. 9-37A). Meningioma is not unusual. Both optic gliomas and meningiomas may occur bilaterally. Bilateral optic gliomas are almost pathognomonic of neurofibromatosis (Fig. 9-38), whereas bilateral meningiomas are only suggestive of neurofibromatosis. Orbital schwannoma, neurofibroma, and neurofibrosarcoma also can be seen in these patients.

Orbital (Mesodermal) Defects

Osseous dysplasia of the cranial bones, in particular the bony orbit, may be part of the abnormality associated with von Recklinghausen's disease. The orbital defect is a consequence of partial or complete absence of the greater or lesser wing of the sphenoid bone, or both. The body of the sphenoid bone may also be involved, producing

Copyright © 2003, Mosby, Inc. All rights reserved.

an abnormal and dysplastic sella turcica (Fig. 9-37).[33, 60] These osseous abnormalities allow the adjacent temporal lobe of the brain and its overlying, often thickened dural membrane to herniate anteriorly into the posterior aspect of the orbit, causing anterior displacement of the globe (Fig. 9-37). The normal CSF pulsations are transmitted to the globe, resulting in pulsatile exophthalmos. Associated findings include hypoplasia of the ipsilateral frontal and maxillary sinuses and hypoplasia of the adjacent ethmoid air cells.[33, 60]

Mandibulofacial Dysostosis

Orbital Defects

The malformation known as *mandibulofacial dysostosis* (MFD) was first reported in 1889 by an ophthalmologist, G.A. Berry.[63] Treacher Collins, whose name is attached to the disease of MFD, described the disease and noted the characteristic malar hypoplasia and the associated flattening of the cheeks.[64] In 1923, Pires de Lima and Monteior stated that MFD probably is due to a developmental defect affecting the branchial arches (the hallmark of MFD is its varied expressivity).[65] Franceschetti and Klein, who coined the name *mandibulofacial dysostosis*, classified the syndrome into five separate categories: complete, incomplete, abortive, unilateral, and atypical.[66] Gorlin et al. stated that there is no unilateral form of the syndrome and that such cases are better classified as hemifacial microsomia.[37] Poswillo, in his experimental study of a teratogenically induced phenocopy of MFD in an animal model, showed that the disorder results from disorganization of the preoptic neural crest at about the time of migration of cells to the first and second branchial arches.[67] There are now several recognized malformations in which abnormalities of the eye and associated abnormalities of structures derived from the first and second branchial arches are found.

VIEW IMAGE

FIGURE 9-34 Crouzon's disease. Coronal MR image shows the striking harlequin appearance of the orbits caused by elevation of the roofs and lateral walls or orbits. Note the deformity of the extraocular muscles and hypoplasia of the midface. One or more extraocular muscles may be absent in Crouzon's or Apert's disease.

Bony Orbital Defects

In MFD the maxilla and malar bones are usually poorly developed, with small antra and shallow or incomplete orbital floors (Fig. 9-39A).[50] The malar bones are hypoplastic, and the zygomatic arches are usually incomplete. The development of the zygomatic process of the maxilla varies among the cases described, and it may not be developed. The radiographic orbital characteristics of MFD are the downward-sloping floors of the orbits in line medially with a beak-like bony nasal contour. The lateral and lower rim of the orbit is often defective (Fig. 9-39A). CT shows the deficiency of the lateral orbital floor as an orbital cleft that varies considerably in degree. The greater wings of the sphenoid may be hypoplastic, and therefore the lateral orbital wall may be defective (Fig. 9-39A). Herring et al. reported a patient with MFD who had hypoplasia of the greater wing of the sphenoid and in whom the temporal squamous bone extended anteriorly, beyond its usual boundaries, to replace the very hypoplastic greater wing of the sphenoid.[68] The squamous bone articulated directly with the frontal bone, at the anterior end of the temporal fossa, and formed a section of the lateral orbital wall. In MFD the infraorbital foramen may be absent, the fossa of the lacrimal sac may be larger than normal, and the nasolacrimal canal is usually short.[68] The lacrimal bones are normal.

Bony Orbit in Craniofacial Microsomia

Craniofacial microsomia is known by many names, including *first and second branchial syndrome*, *otomandibular dysostosis*, and *oculoauriculovertebral dysplasia*.[37, 50, 69] In general, among the congenital oculoauriculocephalic syndromes, the term *first and second branchial arch syndrome* designates a characteristic congenital malformation that is usually unilateral but occasionally is bilateral. The term *hemifacial microsomia* was advocated by Gorlin et al. to refer to patients with unilateral microtia, microsomia, and failure of formation of the mandibular ramus and condyle.[37] Hemifacial microsomia includes as a variant of this complex such malformations as Goldenhar's syndrome and oculoauriculovertebral dysplasia, previously described as separate entities.[37] About 10% of the patients have bilateral involvement, but the disorder is nearly always more severe on one side.[37] The associated eye findings that are considered variable features of this syndrome include epibulbar dermoids or lipodermoids, microphthalmia, coloboma of the choroid and iris, and deformity of the bony orbit similar to MFD as a result of hypoplasia of the maxilla and malar bone.

Developmental Orbital Cysts

The most frequent developmental cysts involving the orbit and periorbital structures are the dermoid and epidermoid cysts, choristomas, and teratomas.[3, 8, 17, 70–72] The relative frequency of these cysts compared to other orbital lesions is shown in Table 9-2. The age distribution of the common orbital diseases is shown in Table 9-3. Choristoma is a focus of tissue histologically normal for an organ or part of an organ at a site other than the site at which it is located.[5, 6, 73] A dermoid or epidermoid cyst is a choristoma that may be found in several locations in the orbit. Lipodermoids are solid tumors that are usually located beneath the conjunctiva over the lateral surface of the globe.[5, 6] A conjunctival lipodermoid is a true choristoma, since (adipose) fatty tissue usually is not found in this region. Conjunctival choristomas are relatively common congenital lesions that possess little growth potential. They contain both dermal and epidermal elements that are not normally found in the conjunctiva.[74] Three types of conjunctival choristomas are found—the solid limbal dermoid, the more diffuse dermolipoma, and the complex choristoma. Solid limbal dermoids typically occur unilaterally, at the inferotemporal limbus. Dermolipomas (lipoder-

moids) are less dense than solid dermoids and contain more adipose tissue. Typically they are found on the superior temporal bulbar conjunctiva near the levator and extraocular muscles[5, 6] (Fig. 9-40). These masses can extend from the limbus anteriorly to the posterior aspect of the globe and orbit between the superior and lateral rectus.[74] Care must be taken during surgical removal to avoid rupture of the cyst, with deposition of cells at the operative sites, and in particular not to damage the palpebral portion of the lacrimal gland, extraocular muscles, or levator palpebrae superioris.[73, 74] Bilateral limbal dermoids or dermolipomas are found in children who have Goldenhar's syndrome. Complex choristomas consist of variable combinations of ectopic tissues such as ectopic lacrimal gland, respiratory, eyelid gland, or brain tissues. Epibulbar osseous choristomas are solitary nodules that resemble dermoids. They are composed of mature, compact bone along with other typical choristomatous elements such as pilosebaceous units and hair follicles.[74] Dermoid and epidermoid cysts are choristomas that are among the most common orbital tumors of childhood. Both may be found in several locations in the orbit, most frequently superior and temporal. The tumor is congenital but may not be noted at birth. Many become evident only in the second and third decades.[6] Both result from the inclusion of ectodermal elements during closure of the neural tube. The dermal elements that are pinched off along the suture lines, diploe, or within the meninges or scalp in the course of embryonic development give rise to

these cysts.[6, 71] Both have a fibrous capsule with varying degrees of thickness. The epidermoid has a lining of keratinizing, stratified squamous epithelium. The dermoid contains one or more dermal adnexal structures such as sebaceous glands and hair follicles. Some dermoid cysts may also contain lobules of fat. These dermoid cysts should be considered well-differentiated teratomas, because they contain tissue derived from more than a single embryonic germ layer. Teratomas are choristomatous tumors that contain tissues representing two or more germ layers. Endodermal derivatives such as gut or respiratory epithelium, ectodermal tissues such as skin and its appendages, and neural and mesodermal tissues such as connective tissues, smooth muscles, cartilage, bone, and vessels may be present. These developmental cysts represent 24% of all orbital and lid masses, 6% to 8% of deep orbital masses, and 80% of cystic orbital lesions.[75] These cysts may contain fluid or solid components.[73, 76] Teratomas are evident at birth as grossly visible cystic orbital masses.[8, 71] Teratomas are tumors composed of cells originating from more than one embryonic germ layer and situated in a site that is not the normal location for the cells.[73] Orbital teratomas may arise from pluripotential stem cells delivered to the orbit hematogenously or from stem cells displaced during their migration.[73] The tumors can be both solid and cystic. However, they are usually cystic and can cause dramatic exophthalmos at birth. Although teratomas in other sites such as testes are commonly malignant, teratomas within the orbit are rarely malignant.[73] Orbital teratomas tend to affect girls, are unilateral, grow rapidly, and are not associated with other anomalies. Although exenteration is sometimes performed

because of the fear of malignancy, cystic teratomas can sometimes be removed with preservation of the eye.[6] Intraocular teratomas are distinctly rare and may appear similar to the teratoid medulloepithelioma, a usually benign tumor of the ciliary body and rarely of the optic disc and nerve, which is seen in young children. The dermoid and epidermoid cysts favor the upper portion of the orbit for their growth (Figs. 9-41 and 9-42). They grow slowly; however, at times these cysts can grow rapidly, particularly in adults.[72] They are most frequently located at the superior temporal quadrant of the orbit, where they are fixed to the periosteum near the frontozygomatic suture line (Figs. 9-41 and 9-42A,B).[70–72] Occasionally, they can be found at the frontoethmoidal or frontonasal sutures and can simulate an encephalocele (Fig. 9-42C).[6] These cysts may be entirely confined to the orbital adnexal tissues. Most of them appear clinically during childhood and present as subcutaneous nodules near the orbital rim. In adults the cysts most commonly arise behind the orbital rim, often near the lacrimal gland, and may be difficult to distinguish from lacrimal gland tumors.[71, 72] The cysts may contain cystic or solid components.

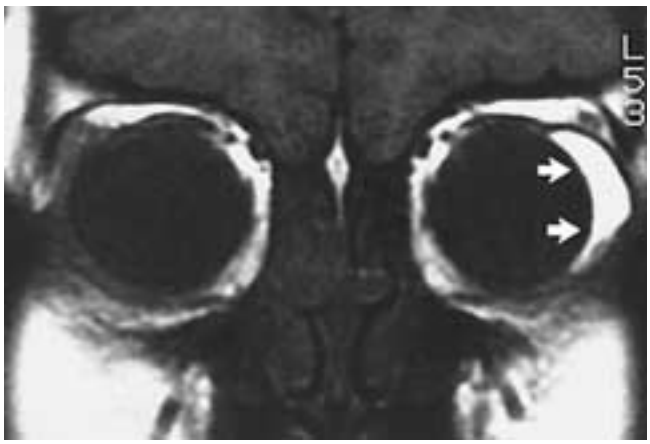

FIGURE 9-40 Coronal T1-weighted MR image shows a hyperintense mass (*arrows*) compatible with a dermolipoma. (From Kaufman LM et al. Diagnostic imaging of cystic lesions in the child's orbit. Radiol Clin North Am 1998;36:1149–1163.)

VIEW IMAGE

Diagnostic Imaging

The imaging modality of choice depends on the entity being considered. When a prominent feature of the suspected lesion is bone remodeling, bone destruction, bone or calcium deposition, or intralesional fat, CT scanning is indicated (Fig. 9-41). MR imaging may provide information about the characteristics of fluid and tissues within the cystic lesion. Both epidermoid and dermoid cysts appear on CT as unenhanced, well-circumscribed, smoothly marginated, low-density masses (Figs. 9-41, 9-42). If a dermoid cyst contains fatty tissues (well-differentiated teratomas), it has fat density on CT (Fig. 9-42A). Similarly, calcifications may be seen within these dermoid cysts. Calcification is not a feature of epidermoids. Although rare, we have seen calcification in intracranial epidermoid but not in orbital epidermoid cysts. Fat-fluid levels may be present in dermoid cysts. A ruptured dermoid/epidermoid cyst shows surrounding inflammatory changes. Some dermoid cysts may appear moderately to markedly hyperdense on CT scans. On MR imaging, dermoid and epidermoid cysts have low signal intensity on T1-weighted MR images and high signal intensity on T2-weighted, flair as well as diffusion-weighted MR images (Fig. 9-41B). A dermoid cyst that contains significant fatty tissue demonstrates the MR characteristics of fat (Fig. 9-42B). Both dermoid and epidermoid cysts may demonstrate marginal enhancement of their wall on postcontrast CT and MR images. The CT and MR imaging features of these lesions are shown in Table 9-4.

Table 9-4
CT AND MR IMAGING FEATURES OF ORBITAL CYSTS

Diagnostic Group	CT Characteristics	MR Imaging Characteristics
Epidermoid cyst	Nonenhancing mass with or without bone erosion Scalloping with sclerosis of the adjacent bone may be present No calcification Minimal enhancement of the capsule may be present	Hypointense on T1-weighted and hyperintense on T2-weighted images Minimal enhancement of capsule may be present Associated orbital inflammatory changes, when cyst is ruptured
Dermoid cyst	Nonenhancing mass with or without bone erosion Scalloping with sclerosis of the adjacent bone may be present Calcification, if present, is a characteristic feature Hypodensity (fat), if present, is characteristic (adipose tissue) Fat-fluid level may be present and is characteristic Minimal enhancement of the capsule may be present	Hypointense on T1-weighted and hyperintense on T2-weighted images Those containing fat demonstrate signal characteristics of fatty tissue Minimal enhancement of capsule may be present Associated orbital inflammatory changes, when cyst is ruptured
Conjunctival choristoma (dermolipoma)	Density of adipose tissue	Intensity of adipose tissue
Cholesterol granuloma (chronic hematic cyst)	Nonenhancing mass with or without bone erosion Lytic lesion with ragged bone destruction Often isodense to brain No sclerotic margin	High signal on T1-weighted and T2-weighted images Often homogeneous in signal characteristics Heterogeneous signal, particularly on T2-weighted images
Enterogenous cysts	Isodense or hyperdense, depending on the mucous content of the cyst	Hypointense or hyperintense on T1-weighted images, depending on the mucous content of the cyst, and hyperintense on T2-weighted images
Other orbital epithelial and appendage cysts, including implantation cysts	Nonenhancing low-density mass	Nonenhancing, hypointense on T1-weighted and hyperintense on T2-weighted images
Congenital cystic eye	Nonenhancing low-density mass	Hypointense on T1-weighted and hyperintense on T2-weighted images Nonenhancing mass
Dacryocele	Nonenhancing (unless infected) low-density mass	Hypointense on T1-weighted and hyperintense on T2-weighted images; nonenhancing mass, unless infected
Parasitic cysts (hydatid, cysticercosis)	Cystic lesions within or near an EOM Some degree of enhancement around the cyst wall Scolex can be identified Diffuse myositis may be present Cystic lesion within or near lacrimal gland or other part of the orbit	Cystic lesions within or near an EOM Hypointense on T1-weighted and hyperintense on T2-weighted images Some degree of enhancement around the cyst wall Scolex can be identified Diffuse myositis may be present

Other Less Common Congenital Anomalies and Acquired Cysts of the Orbit and Optic System

The orbit develops from mesodermal tissues, and the globe and optic pathway develop from ectodermal tissues. Developmental defects of the eyeball result in a small orbit. The majority of orbital changes are found in association with deformities of the skull (Fig. 9-30) and skeleton.[36] Cyclopia, synophthalmia, clinical anophthalmia, and microphthalmia (Figs. 9-30 and 9-31) are developmental anomalies of the globe that are seen in the fetal central system anomalies associated with problems in forebrain differentiation (holoprosencephaly). MR imaging is particularly noteworthy in the detection of these anomalies. In general, a variety of cysts and cyst-like lesions involve the orbit. The list includes developmental anomalies as well as acquired lesions arising in the orbit or in adjacent structures.[73] A *cyst* is defined as a closed sac with a membranous or cellular lining and a luminal space containing air, fluid, semifluid, or solid materials. Cysts typically result from developmental anomalies, obstruction of ducts, or parasitic infections or trauma, as listed in Table 9-5.

Congenital Cystic Eye

Congenital cystic eye is a rare congenital anomaly resulting from failure of the optic vesicle to invaginate during the fourth week of embryogenesis.[73] It presents at birth as a complex cyst occupying the orbit, without any vestige of a globe (Fig. 9-43). The cyst wall is lined by cells derived from undifferentiated retina and retinal pigment epithelium. Some remnant of an optic nerve–like structure and extraocular muscles may be present.[73] CT and MR imaging generally show an enlarged orbit containing a rounded or ovoid, septated cyst (Fig. 9-43). The superior orbital fissure may be enlarged (widened) ipsilaterally. On MR imaging, the signal intensity of the cyst may not be equal to that of the normal vitreous, because the cyst is generally filled with serum. A rudimentary connection to a thinned optic nerve may be seen. A nodular focus may be seen adjacent to the cyst wall, representing primitive ectopic lens tissue.[73] In the colobomatous orbital cyst, unlike the congenital cystic eye, the globe and optic nerve are seen on CT and MR imaging. The globe is, however, microphthalmic (Fig. 9-44). Orbital colobomatous cysts are described in Chapter 8.

Other Orbital Cysts

Optic Nerve Sheath Meningocele

Optic neural sheath meningocele (optic nerve sheath cyst, arachnoid cyst, perioptic hygroma, and dural ectasia, among others) is a saccular dilatation of the meninges surrounding the orbital portion of the optic nerve.[77] These meningoceles may occur primarily or secondarily in association with other orbital processes, such as meningioma, optic nerve pilocytic astrocytoma, and hemangioma. Clinically, these meningoceles may present with changes in visual acuity, visual field, and optic nerve appearance. The CT and MR imaging appearance of optic nerve meningocele or ectasia is that of a prominent focal or segmental enlargement of the dural arachnoid sheath around the optic nerve (Fig. 9-45). The optic nerve dural ectasia may be associated with an empty sella and enlarged subarachnoid cisterns, such as gasserian cisterns (Fig. 9-46).

Cephaloceles include meningocele, encephalocele, meningoencephalocele, and porencephalic cyst.[73] A cephalocele is a cyst-like herniation of brain or meningeal tissues into adjacent structures. The lesions are commonly congenital but can also be due to acquired defects in the bony orbit. The herniated tissue may be limited to meninges (meningocele); brain parenchyma (encephalocele); brain and meninges (meningoencephalocele); or expanding porencephalic cysts. Brain tissue may herniate into the orbit via natural orbital foramina, such as the superior orbital fissure; through dehiscences of the cranial sutures; or through bony orbital defects, such as those seen in patients with neurofibromatosis type 1. When a cleft associated with a midline craniofacial dysraphism affects the nose, there is an increased incidence of frontonasal and intraorbital encephaloceles, anophthalmos, or microphthalmos. Hypertelorism and a broad nasal root are also found in nearly all affected individuals.[73] MR imaging remains the study of choice to illustrate cephaloceles.

	Aneurysmal bone cyst
	Cystic myositis
	Orbital abscess
	Parasitic cyst (hydatid cyst, cysticercoses)

Enterogenous Cysts

Enterogenous cysts are rare congenital choristomatous cysts of the central nervous system. They contain a single layer of mucin-secreting epithelial cells that resemble gastrointestinal epithelium. The lower cervical and cervicothoracic regions are the more common sites of the lesion. An orbital location is extremely rare.[78] Occasionally these cysts may be seen in the anterior cranial fossa and extending into the orbit. CT shows a well-circumscribed, homogeneous, rather hyperdense, lobular, nonenhancing mass. Extension through the superior orbital fissure may be present. Bony erosion due to compressive bone atrophy or bony remodeling including the greater wing of the sphenoid bone and ethmoid roof may be present. On MR imaging, the lesion usually appears hyperintense on T1-weighted images due to the mucous secretions elaborated by the epithelial lining cells. The T2-weighted MR images may show variable signal intensity, depending on the protein content of the fluid within the cyst. Enhancement of the mucosal rim may be seen on enhanced CT and MR images.[78]

Dentigerous Cysts

Dentigerous cysts, fluid-filled and lined by keratinizing (keratogenic cysts) or nonkeratinizing, stratified squamous epithelium, arise from the jaw. Infrequently, the cyst can enlarge into the maxillary sinus and erode into the orbit. These cysts appear as a nonenhancing low-density mass on CT scans. On MR imaging they appear with a low to intermediate signal on T1-weighted MR images and hyperintense on T2-weighted MR images. The signal characteristics on T1-weighted MR images depend on the cyst's protein content.

Cystic Vascular Lesions: Lymphangioma, Varix, Chocolate Cyst

Lymphangioma and varix will be described later in this chapter. Lymphangiomas contain numerous variably sized cystic spaces. Acute hemorrhage into these cystic spaces, whether spontaneous or after minor trauma, results in chocolate cysts. A varix is a venous anomaly and may include a single smooth-contoured, dilated vein. Intralesional hemorrhage in an orbital varix may result in the formation of a chocolate cyst.[73]

Epithelial and Appendage Cysts

Various acquired cysts involving the eyelids or superficial orbit may derive from the skin of the eyelids, the skin appendages (glands and cilia), or the conjunctiva.[73] Common in children is the chalazion, a cystic expansion at the meibomian sebaceous gland due to a blockage of its excretory duct. Other cysts include apocrine hidrocystoma (sudoriferous cyst), originating from a blocked excretory duct of Moll's apocrine sweat gland; eccrine hidrocystoma, derived from the lid eccrine sweat gland; sebaceous cyst (pilar cyst, retention cyst of the pilosebaceous structure); milia (cystic expansion of the pilosebaceous structure due to obstruction of the orifice); epidermal inclusion cyst (cutane-

ous or subcutaneous cyst lined by stratified squamous epithelium with a keratin-filled lumen); pilomatrixoma (calcifying epithelioma of Malherbe, a solid or cystic mass derived from hair matrix cells); and conjunctival inclusion cyst (a thin-walled, fluid-filled cyst lined by stratified, nonkeratinizing, cuboidal epithelium containing mucus-secreting goblet cells). Because most epithelial and appendage cysts remain small (less than 1 cm) and limited to the eyelid and the superficial orbit, medical imaging studies are rarely ordered by the ophthalmologist.

Epithelial Implantation Cysts

Epithelial implantation cysts are derived from cells of the cutaneous epithelium, conjunctival epithelium, or respiratory epithelium that are traumatically displaced under the skin of the eyelid or into the orbit. The CT and MR imaging appearance of these cysts is nonspecific and similar to that of any simple cyst (Fig. 9-47). A nonenhanced cystic orbital mass following orbital surgery or enucleation should raise the question of the presence of an epithelial implantation cyst.

FIGURE 9-46 Ectasia of the optic nerve sheath. T2-weighted MR image shows marked expansion of the subarachnoid space around the right optic nerve (*arrow*). Lacrimal Gland Cysts

Cysts of the lacrimal glands can be due to blockage of the gland's excretory ducts.[73] The cyst is then located in either the orbital or the palpebral lobe of the main lacrimal gland, or in the conjunctival fornices due to blockage of the accessory lacrimal glands of Krause and Wolfring.[73] The CT and MR imaging appearance of lacrimal gland cysts is similar to that of any simple cyst (Figs. 9-48 and 9-49).

Dacryoceles

A dacryocele (lacrimal sac mucocele) is a cystic expansion of the nasolacrimal sac or a diverticulum of the sac. The expansion is caused by a proximal or distal block of the nasolacrimal duct. Dacryoceles are considered a congenital anomaly of the lacrimal drainage system and are usually apparent in the first few days of life. On CT and MR imaging, dacryoceles appear as well-circumscribed, rounded lesions centered in the nasolacrimal sac region. On CT scans, the density of the lesion is homogeneous when noninfected. On MR imaging, a dacryocele appears hy-

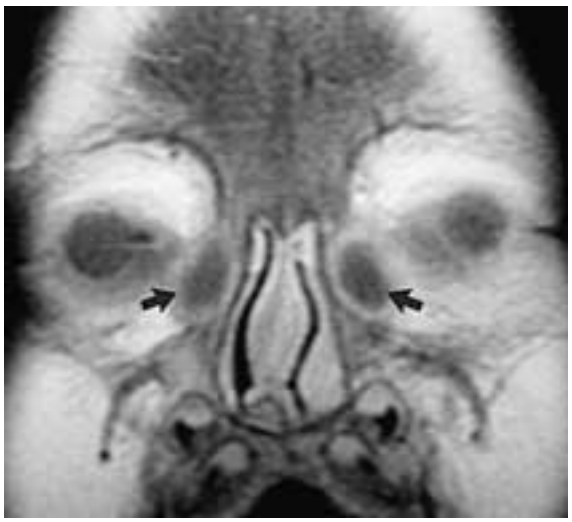
pointense on T1-weighted and hyperintense on T2-weighted images. If it is infected, there may be a rim of contrast enhancement (Fig. 9-50).

Hematic Cysts and Cholesterol Granuloma

Most orbital hematomas, like other localized collections of blood, resolve within days. The hematic cyst (organizing hematoma, hematocele), is a cyst-like mass that develops slowly as an acute orbital hemorrhage, is incompletely absorbed, and undergoes organization.[73] There may be a fibrous cyst wall with a lumen composed of degraded blood products, cholesterol, hemosiderin, hematoidin crystals, erythrocytes, histiocytes, giant cells, and granuloma tissue. The hematic cyst may occur anywhere in the orbit or in the orbital bones (cholesterol granuloma).[73, 79] The subperiosteal compartment of the orbit, a potential space, is an important entity due to its unique anatomy, location, and susceptibility to various pathologic processes, such as



VIEW IMAGE

hemorrhage, infection, infiltration of lymphoproliferative disorders, infiltration of en plaque meningiomas, and metastasis.[17, 79] The etiology of subperiosteal hematomas is either traumatic or spontaneous. Traumatic hemorrhage is most common, but the time interval between the traumatic episode and the clinical manifestation may vary from immediate to months or years.[17, 79] Spontaneous hemorrhage can occur as a complication of leukemia, thrombocytopenia, blood dyscrasia, hemophilia, anticoagulant use, and other hemorrhagic systemic diseases, including sickle cell anemia.[79] Subperiosteal hematomas can be of several varieties. Acute subperiosteal hematoma is a rare complication of trauma, presenting as painful unilateral proptosis.[79] It may also develop so insidiously as to defy explanation, especially when there is no definite history of injury. Usually it is the result of bleeding from the subperiosteal blood vessels.[79] It may also develop as an extension of a subgaleal hematoma. At times it is continuous with an epidural hematoma after head trauma. In cases of trauma, blood tends to collect in the subperiosteal location superiorly, as the frontal bone is the largest continuous concave surface of the orbit and has a loose periosteal attachment.[79]

Diagnostic Imaging

CT is a very accurate diagnostic method to evaluate subperiosteal hematomas. Coronal sections, either direct or reformatted, are essential for accurate diagnoses. The CT appearance of acute and subacute subperiosteal hematomas is that of a sharply defined extraconal, homogeneous, high-density, nonenhancing mass with a broad base abutting the bone and displacing the peripheral orbital fat toward the center of the orbit (Figs. 9-51 to 9-53). The mass, like other subperiosteal lesions, is fusiform or biconvex, is confined by the sutures (frontozygomatic or frontoethmoidal), and is best seen in coronal or sagittal images. Prompt aspiration of the hematoma can lead to early decompression and prevent serious late sequelae. A chronic subperiosteal hematoma appears on CT as a heterogeneous, relatively hypodense, sharply defined extraconal mass with a broad base (Fig. 9-54). Long-standing chronic hematic cysts, the so-called cholesterol granulomas, appear as cystic lesions, associated with compression bone atrophy as well as expansion and erosions of adjacent bone (Fig. 9-55). On a CT scan, chronic hematic cysts may not be differentiated from epidermoid-dermoid cysts (Fig. 9-10). However, they can be easily differentiated by MR imaging (Fig. 9-56).

MR Imaging Findings in Various Stages of Orbital Hematoma

The diagnosis of hematoma is greatly aided by MR imaging, which can characterize all stages of blood degradation. The iron atoms of hemoglobin have a different magnetic effect, depending on the physical and oxidative state of the hemoglobin itself.[80] Fresh (hyperacute) oxygenated blood (hemorrhage no more than a few hours old) has approximately the same MR imaging characteristics as water, being hypointense on T1-weighted and hyperintense on T2-weighted images, using a high field (1.5 Tesla) MR unit. Acute hemorrhages (1 to 7 days old), because of the paramagnetic effect of deoxyhemoglobin, have a low signal on T1-weighted and in particular on T2-weighted images

(Fig. 9-51). With progressive oxidation of deoxyhemoglobin to methemoglobin, hemorrhages older than 7 days become hyperintense on T1-weighted images (Fig. 9-56). The signal on T2-weighted MR images remains low if the methemoglobin is still intracellular (i.e., if oxidation occurred before erythrocyte lysis), therefore having limited motion. The signal is high if the methemoglobin has become extracellular (Fig. 9-56). Hemosiderin, which causes a low signal on both T1-weighted and T2-weighted sequences, is encountered in scars or organized hematoma.[80] The MR imaging of hematoma is presented in Table 9-6.

Orbital Cholesterol Granuloma

Cholesterol granulomas are bone-pushing and bone-destroying lesions characterized by granulomatous infiltration surrounding cholesterol crystals. The cholesterol granuloma may be etiologically related to the loss of aeration of normally pneumatized bone, such as the petromastoid bone. Negative pressure develops, leading to tissue edema and hemorrhage. Rupture of red blood cell membranes results in precipitation of cholesterol and membrane phospholipids. This crystallized cholesterol, in turn, acts as a foreign body and elicits a giant cell

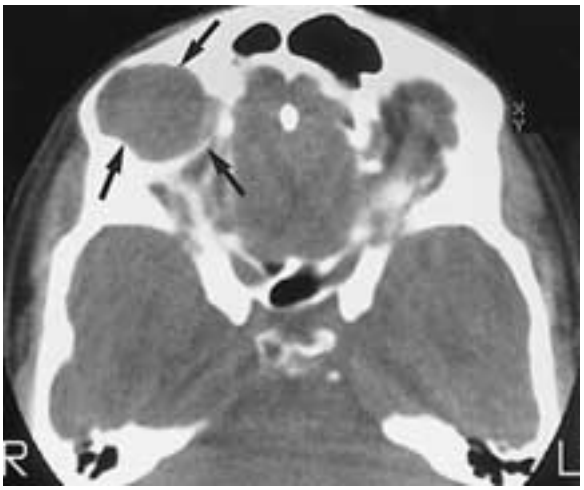
granulomatous reaction. Histologically, there are no epithelial elements in the cholesterol granuloma. Histologically, the tissues consist of foci of reactive xanthogranulomatous infiltrates, cholesterol crystals, giant cells, and hemosiderin surrounded by a fibrous capsule (Fig. 9-55B). The initiating factors must be different in the lesions arising in nonpneumatized bone from those in the orbital region. In the orbit, cholesterol granulomas are secondary lesions that are formed due to a posttraumatic, postsurgical, or postinflammatory event. Various terms have been used to describe cholesterol granuloma including *lipid granuloma*, *cholesteatoma*, *xanthomatosis*, *histiocytic granuloma*, and *chronic hematic cyst*. Cholesteatomas are considered epidermoid cysts and should not be confused with cholesterol granulomas.

Diagnostic Imaging. On CT, cholesterol granulomas are seen as lytic lesions, usually with ragged bone destruction, that invariably extend extraperiosteally into the orbit, causing proptosis (Fig. 9-55A). Extension into the anterior and middle cranial fossae occurs less frequently.[79] On CT scans, the density of a cholesterol granuloma is approximately isodense with the brain, with the attenuation values ranging from 25 to 45 HU (mean, 34 HU). Unlike epidermoid cyst, no sclerotic margin is seen between the mass and normal diploic bone. The lesion demonstrates no enhancement on postcontrast CT scans. The differential diagnosis on the basis of CT scanning is limited to epidermoid and dermoid cysts or aneurysmal bone cyst. Aneurysmal bone cysts occur almost exclusively in children.[79] MR imaging can be of most value in the diagnosis of cholesterol granuloma. These lesions give rise to high signal on T1-weighted and T2-weighted sequences, characteristic of chronic hemorrhage (Fig. 9-57).[79]



VIEW IMAGE

Aneurysmal Bone Cysts

The term *aneurysmal bone cyst* (ABC) is a misnomer, because the lesion is histologically neither an aneurysm nor a cyst. Infrequently, ABC of the facial bones may involve the orbit in children.[73] ABC has been described as a benign lesion of bone characterized by a blood-filled cyst-like expansion within the bone. The expansion may be complex and multilobular, with septae of bony trabeculae, fibrous tissues, and stromal giant cells. The lesions remodel adjacent bone, but the surrounding periosteum remains intact. ABC is not an entity by itself but is always secondary to an underlying bony or fibroosseous condition, such as nonossifying fibroma, ossifying fibroma, fibrous dysplasia, juvenile pseudomonatous active (aggressive) ossifying fibroma (Fig. 9-58), chondroblastoma, chondromyxoid fibroma, osteoblastoma, giant cell tumor (osteoclastoma), fibrosarcoma, osteochondrosarcoma, hemangioendothelioma, or hemangioma.[73]

Cystic Myositis

Infrequently, nonspecific orbital myositis may result in cyst-like changes in an extraocular muscle.[73] These cysts may respond to treatment with oral corticosteroids, suggest-

Copyright © 2003, Mosby, Inc. All rights reserved.

ing that the cysts do not have a parasitic origin and probably represent edema in the muscles.[73]

Orbital Abscesses (Inflammatory Orbital Cysts)

Orbital abscesses are cyst-like pus pockets that develop subperiosteally, or in the orbit or lids, in association with orbital or preseptal cellulitis most often associated with sinonasal infections (Fig. 9-59). The CT and MR imaging of orbital abscesses will be described in a following section.

Parasitic Cysts

Hydatid Cysts

The occurrence of parasitic orbital cysts is limited to endemic regions with poor sanitation. The hydatid cyst is related to infection by the larval form of a parasitic tapeworm, *Echinococcus granulosus*. The adult worm lives in the intestines of carnivores (usually dogs but not humans). The infected carnivore passes the worm's ova in its feces. Grazing animals, acting as intermediate hosts, ingest the

ova, which develop into larval forms in the hosts' muscles. Humans are infected by eating the undercooked meat of an infected grazing animal. Traveling via the bloodstream, the hydatid can lodge in the orbit, resulting in a well-defined cystic mass with or without a fluid-fluid level containing the parasite. Clinically, patients present with slowly progressive, painless orbital signs.[73, 81]

Cysticercosis

Cysticercosis is a disease due to infestation by *Cysticercus cellulosae*, the larval form of the parasitic tapeworm *Taenia solium*. Clinically, patients present with either a visible subconjunctival cyst or orbital signs due to an extraocular muscle cyst that is unresponsive to treatment with oral corticosteroids.

Diagnostic Imaging

The CT and MR imaging characteristics of most parasitic cysts are nonspecific. There may be some degree of enhancement around the cyst wall.[73, 81] Nearly all patients with orbital cysticercosis examined by CT show a cystic lesion near or within an extraocular muscle. An intraocular mass or cyst may be present.[82] A scolex can be identified within the cystic lesions in nearly one half of patients by CT or MR imaging and is diagnostic (Fig. 9-60). CT or MR imaging evidence of a cystic lesion without a scolex or diffuse myositis in the presence of a positive enzyme-linked immunosorbent assay for anticysticercal antibodies is also diagnostic. Concurrent neurocysticercosis and orbital cysticercosis appear uncommonly (Fig. 9-60). Neurocysticercosis is generally associated with more morbidity than orbital cysticercosis.[73]

INFLAMMATORY DISEASES

Orbital infections account for about 60% of primary orbital disease processes.[3] The infection may be acute, subacute, or chronic. The majority of acute inflammatory disorders are of paranasal sinus origin. However, the

FIGURE 9-58 Aggressive psammomatoid ossifying fibroma. **A**, Coronal CT scan shows a large, expansile mass of mixed intensity. Note the psammomatoid bodies (*arrows*). **B**, Coronal CT scan in another patient shows an ossifying fibroma (*arrows*). The lesion is less aggressive than the lesion shown in **A**. Note the CT appearance of the psammomatoid bodies (*arrowheads*). **C**, Coronal CT scan in a 18-month-old child shows a soft-tissue mass, with involvement of the medial wall of the orbit as well as the roof of the ethmoid bone. Note the intralesional islands of calcification (*arrows*). Pathologic diagnosis was felt to be most consistent with an aggressive fibro-osseous lesion (fibrous dysplasia versus ossifying fibroma). (From Mafee MF et al. Fibro-osseous, osseous, and cartilaginous lesions of the orbit and paraorbital region. Radiol Clin North Am 1998;36:1241.)

infection may develop from infectious processes of the face or pharynx, trauma, or foreign bodies, or it may be secondary to septicemia. Nearly two thirds of orbital infections are estimated to occur secondary to sinusitis, and about one fourth of the infections are due to orbital foreign bodies. The bacteria most commonly involved are *Staphylococcus*, *Streptococcus*, *Pneumococcus*, *Pseudomonas*, Neisseriaceae, *Haemophilus*, and mycobacteria.[83, 84] Herpes simplex and herpes zoster are the major viral infections of the orbit. In immune-suppressed or immunocompromised patients and poorly controlled diabetic patients, opportunistic infections such as fungal and parasitic pathogens may be responsible for severe sinonasal-orbital infections. Acute inflammation is characterized by rapid onset associated with soft-tissue swelling and infiltration, loss of the normal soft tissue planes, local soft-tissue destruction, and abscess formation. The location of the process is clinically important because a preseptal infection (Fig. 9-61) rarely affects orbital functions. On the other hand, a retroseptal (postseptal) infection (Fig. 9-61) may have a profound and sudden

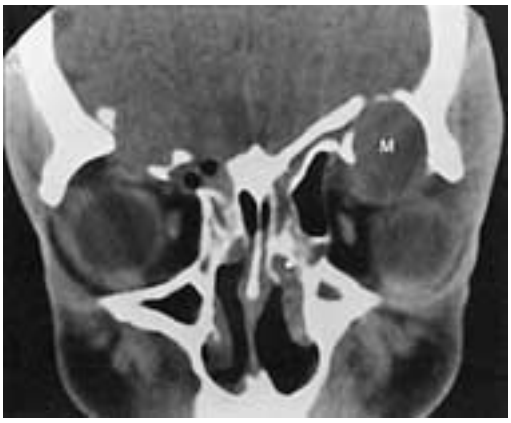

FIGURE 9-59 Extension of a supraorbital ethimoid mucocele into the orbit. Coronal CT scan shows an orbital cystic mass (*M*) related to extension of a mucocele. effect on optic nerve and orbital motility function. Pathologically, in acute bacterial inflammation, polymorphonuclear leukocytes are usually the dominant cells, which, along with their pharmacologic intermediates, lead to necrosis and rapid involvement and destruction of tissue planes.

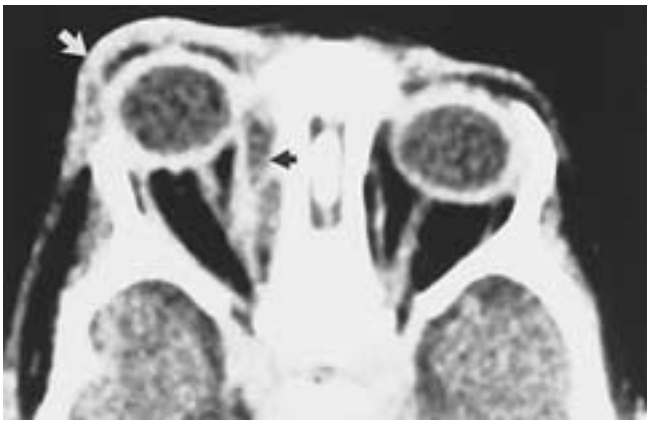
Orbital Cellulitis and Sinusitis

Sinusitis is the most common cause of orbital cellulitis. Even though antibiotics have reduced the incidence of complicated sinusitis with orbital involvement, it still occurs and may be the first sign of sinus infection in children.[71, 83, 84] In the preantibiotic era, morbidity and mortality from orbital cellulitis were significant, with 17% of cases resulting in death and 20% resulting in blindness. Orbital cellulitis is probably the most common cause of proptosis in children.[6] Pathophysiologically, infection originating within the sinuses can spread readily to the orbit via the thin and often dehiscent bony orbital walls and their many foramina or by means of the interconnecting valveless venous system of the face, sinuses, and orbit.[3] The classification of orbital cellulitis includes five categories or stages of orbital involvement: (1) inflammatory edema; (2) subperiosteal phlegmon and abscess; (3) orbital cellulitis; (4) orbital abscess; and (5) ophthalmic vein and cavernous sinus thrombosis.[3, 71, 84] Limiting a particular inflammatory lesion to one of these categories is often difficult because they tend to overlap.[71, 84]



VIEW IMAGE

FIGURE 9-61 Preseptal and retroseptal orbital inflammation. Axial CT scan shows periorbital soft-tissue infiltration and edema (*white arrow*) and retroseptal subperiosteal inflammation and edema (*black arrow*).

Bacterial Orbital Cellulitis Classification

Based upon the anatomy and the presumed pathogenesis of orbital cellulitis of Chandler et al.,[85] classification of the orbital complications of sinus infections is recognized as most useful in clinical situations. The Chandler et al.[85] classification was devised prior to the advent of newer orbital imaging techniques, and modifications that make use of information obtained from these imaging techniques are indicated. We therefore recommend the classification scheme of periorbital infections,[86] outlined in Table 9-7.

Bacterial Preseptal Cellulitis and Preseptal Edema

Preseptal cellulitis defines infections limited to the skin and subcutaneous tissues of the eyelid anterior to the orbital septum.[86] Clinically, the patient has erythema and swelling

Table 9-7
STAGING OF ORBITAL CELLULITIS

State	Clinical Findings
Inflammatory edema	Eyelid swelling and erythema
Preseptal cellulitis	Eyelid swelling and erythema associated with inflammatory soft-tissue thickening of the orbit anterior to the orbital septum
	Chemosis may be present
Postseptal cellulitis	Edema of the orbital contents; proptosis, chemosis, and decreased extraocular movement
	Visual loss (unusual)
Subperiosteal abscess	A collection of inflammatory infiltrates and pus between the periorbita and involved sinuses
	Globe proptotic and displaced by abscess
	Visual loss with progression of the disease
Orbital abscess	Marked proptosis, ophthalmoplegia, and visual loss associated with abscess formation within the orbital fat or muscles
Cavernous sinus thrombosis	Proptosis and ophthalmoplegia with development of similar signs on the contralateral side associated with cranial nerve palsies (nerves III, IV, V, VI) and visual loss

of the eyelids. There is no proptosis, chemosis, or limitation of ocular motility.[86] At a slightly more advanced stage, chemosis occurs. It is unusual for a preseptal infection to traverse the orbital septum and result in postseptal cellulitis.[86] Preseptal edema is the first stage of infection secondary to sinusitis. It is often clinically misdiagnosed as orbital or periorbital cellulitis. The infection in this early stage actually is still confined to the sinus; however, there is swelling of the eyelids with mild orbital edema reflecting congestion of the venous outflow of the eyelid. Usually the upper medial eyelid is affected, and if untreated, preseptal cellulitis will develop. CT or MR imaging demonstrates the eyelid edema and the inflammatory paranasal sinus disease.[8, 84]

Postseptal Orbital Cellulitis

Postseptal orbital cellulitis is an infectious process that occurs within the orbit proper, behind the orbital septum, and within the bony walls of the orbit.[86] Inflammatory edema characterizes the earliest stage of postseptal orbital infection. There is diffuse edema of the orbital contents with inflammatory cells and fluid, but no abscess formation.[86] The swelling of orbital tissues occurs when an increase in sinus venous pressure is transmitted to the orbital vasculature, resulting in transudation and leakage through the vessel walls.[86] Clinically, the patient has eyelid edema, mild proptosis, and chemosis. In severe cases, there may be generalized limitation of motility; however, visual acuity is not impaired.[86] Although contrast-enhanced diagnostic imaging of an isolated preseptal cellulitis usually is not clinically indicated, it can be useful in cases in which the clinical differentiation of preseptal and postseptal cellulitis is impossible or when the diagnosis is unclear.[86] It is important to recognize that based solely on CT and MR imaging, the differentiation between a cellulitis and allergic eyelid edema is impossible, particularly if the paranasal sinuses appear to be clear. The history is always essential in these cases. The CT and MR imaging findings include soft-tissue thickening of the eyelids. Usually the process is diffuse, and a localized eyelid abscess cavity is not seen. In postseptal orbital cellulitis, orbital imaging is indicated and a contrast-enhanced study is necessary to differentiate inflammatory edema, cellulitis, orbital phlegmon, and orbital abscess (Figs. 9-62 to 9-67).

Subperiosteal Phlegmon and Abscess

As the reaction of the orbital periosteum begins and gradually advances, the edema of the eyelids and conjunctivae becomes more generalized and the eye begins to protrude. Inflammatory tissue and edema collect beneath the periosteum to form a subperiosteal phlegmon (Fig. 9-62), which, subsequently, may develop into a subperiosteal abscess (Fig. 9-63). As the disease progresses, the inflammatory process infiltrates the periorbital and retroocular fat, giving rise to a true orbital cellulitis (Figs. 9-64, 9-66, and 9-67). The subperiosteal abscess and orbital cellulitis frequently coexist.[71, 84] At this stage, extraocular motility becomes progressively

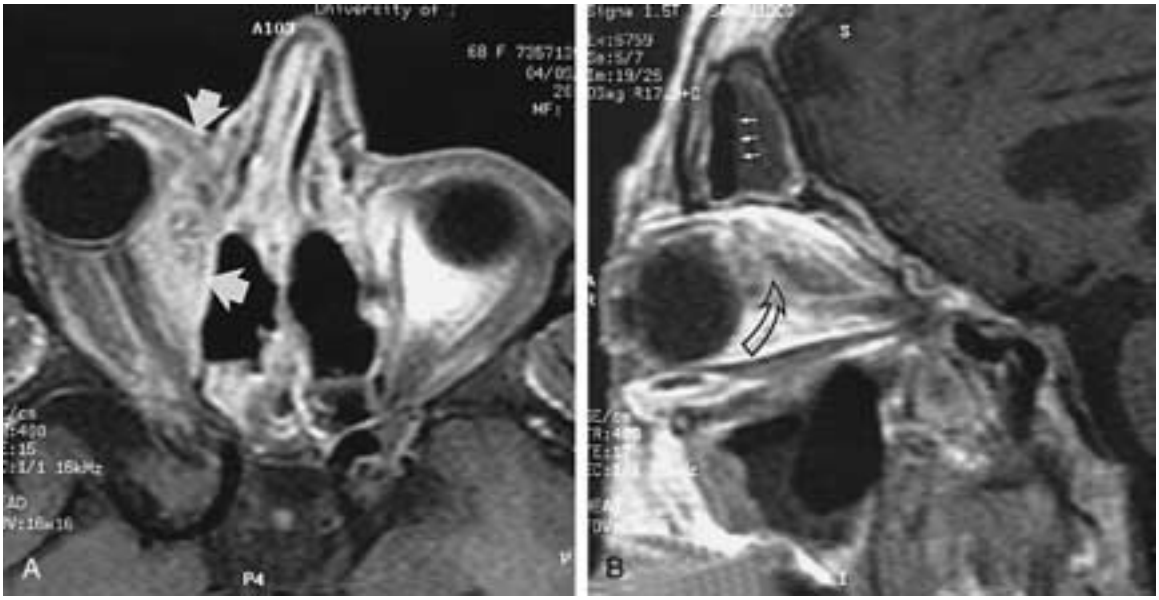
impaired. With severe involvement, visual disturbances can result from optic neuritis or ischemia (Fig. 9-62A). Progression of intraorbital cellulitis or spread from the subperiosteal space leads to intraconal or extraconal loculation and abscess formation (Fig. 9-64).[3, 71, 84] Progression of disease may lead to ophthalmic vein thrombosis (Fig. 9-68), cavernous sinus thrombosis, and associated mycotic aneurysm of the internal carotid artery (Fig. 9-69), all dire complications of orbital and sinonasal infections.

Cavernous Sinus Thrombosis

Cavernous sinus thrombosis (CST) arises from an infection in an area having venous drainage to the cavernous sinus.[83] Thus, the source infection is usually in the sinonasal cavities, in the orbits, and from infections involving the middle third of the face.[86] CST may develop from a septic thrombophlebitis arising in the ophthalmic vein (Fig. 9-68). Proptosis and ophthalmoplegia are common. Offending organisms may be aerobic or anaerobic, with *Staphylococcus aureus* and anaerobic streptococci being the most common organisms. Clinically, patients with CST are extremely ill, demonstrating signs of meningitis and multiple cranial nerve palsies bilaterally.[86] These patients usually have a headache, fever and chills, and an elevated white blood cell count with positive blood cultures.[83] The ophthalmologic findings include edema of the lids, exophthalmos, chemosis, paralysis of the eye muscles, engorgement of the retinal veins, and low-grade papilledema.[83] On contrast-enhanced CT scans, the normal cavernous sinus is seen as an enhancing parasellar structure with a sharply defined lateral border that is either straight or concave toward the adjacent middle cranial fossa. The internal carotid artery cannot normally be separated from the opacified venous sinuses within the cavernous sinus. When thrombosis is present, the cavernous sinus often has a low-attenuation, nonenhancing appearance. The lateral border may bow laterally toward the middle cranial fossa, and the contrast-enhanced internal carotid artery may be seen as a contrast-enhanced tubular structure within the cavernous sinus (Figs. 9-69B,C). Often the superior ophthalmic vein is markedly enlarged and possibly thrombosed. False-negative CT scans are common until late in the course of the disease.[86] Thrombosis of the superior ophthalmic vein (SOV) is seen on MR imaging as an enlarged vein that appears less hypointense than the vein on the normal opposite side. On T1-weighted and T2-weighted MR images, the thrombosed SOV may be seen as a hyperintense area within the lumen of the vein.[87–89] CST results in



VIEW IMAGE

engorgement of the cavernous sinus and ophthalmic veins and usually engorgement of the extraocular muscles.[86] MR imaging and MR venography are more sensitive than CT for revealing CST.[88] On MR imaging there is deformity of the cavernous portion of the internal carotid artery. The signal from the abnormal cavernous sinus is heterogeneous, and there is an obvious hyperintense signal intensity representing the thrombosed vascular sinus that often is seen on all pulse sequences. Mycotic (septic) aneurysm of the internal carotid artery is a serious complication of orbital infection. This can be suspected on CT or MR imaging and confirmed by MR angiography or standard angiography (Fig. 9-69).

Mycotic Infections

Orbital cellulitis secondary to infection with mycotic organisms occurs less frequently than bacterial infections, and usually these patients have a history of uncontrolled diabetes mellitus or are immunocompromised. Immunocompromised patients are particularly susceptible to infection by fungi such as *Candida* species, *Histoplasma capsulatum*, *Coccidioides immitis*, *Mucor*, and *Aspergillus* species.[86] *Mucor* and *Aspergillus* are by far the most

common fungal organisms incriminated. The fungi responsible for mucormycosis are ubiquitous and normally saprophytic in humans; they rarely produce severe disease, except in those with predisposing conditions.[71, 83, 90] There are four major types of mucormycosis: rhinocerebral, pulmonary, gastrointestinal, and disseminated, the most common of which is the rhinocerebral form.[90] The infection usually begins in the nose and spreads to the paranasal sinuses; then it extends into the orbit and cavernous sinuses.[71, 90] Orbital involvement results in orbital signs such as ophthalmoplegia, proptosis, ptosis, loss of vision, and orbital cellulitis.[71] The inflammatory process soon extends along the infraorbital fissure into the infratemporal fossa (Fig. 9-70) and may extend into the cavernous sinuses.

Black necrosis of a turbinate is a diagnostic clinical sign, but it may not be present until late in the course of the disease.[71, 90] The pathologic hallmark of mucormycosis is invasion of the walls of small vessels. For this reason, when the cavernous sinus is invaded, particularly in patients with mucormycosis and aspergillosis, rapid brain infarction may develop.[91]

Aspergillus is a ubiquitous fungus found primarily in agricultural dust. It may produce rhinocerebral disease and orbital involvement similar to that of mucormycosis,

Copyright © 2003, Mosby, Inc. All rights reserved.

although hematogenous spread from the lungs to the brain is more common.[90] This fungus also has a well-known propensity for invading blood vessels, including the internal carotid artery.[71] One important but not pathognomonic MR imaging finding of mycotic infections is the hypointensity of mycetoma on T2-weighted MR images (Fig. 9-71). This is thought to be due to paramagnetic materials produced by the fungi and the semisolid, cheesy nature of the mycetoma.

In general, and in the appropriate clinical setting, a multicentric or unicentric sinusitis with or without bone destruction, and orbital tissues with or without vascular thrombosis, should strongly raise the possibility of sino-orbital mycosis.[86] Although the combination of orbital and sinus involvement is not pathognomonic of rhinocerebral mucormycosis or aspergillosis, awareness of these diagnoses, particularly when any predisposing factors are present, helps establish an early diagnosis. Rapid diagnosis is important because early aggressive treatment is necessary to minimize morbidity and mortality from these usually fatal diseases. The main contribution of CT and MR imaging is their clear demonstration of the relationship between sinonasal, orbital, and intracranial disease (Fig. 9-71). One should realize that the CT and MR imaging findings of invasive aspergillosis are indistinguishable from those of mucormycosis and that advanced sino-orbital mucormyosis and invasive aspergillosis mimic aggressive tumors on CT and MR imaging.

Acute, Subacute, and Chronic Idiopathic Orbital Inflammatory Disorders (Pseudotumors)

Idiopathic inflammatory syndromes usually are referred to as *orbital pseudotumors*, a clinically and histologically confusing category of lesions.[3] In general, orbital pseudotumors represent a nongranulomatous inflammatory process in the orbit or eye with no known local or systemic causes.[92–94] This is a diagnosis of exclusion based on the history, the clinical course of the disease, the response to steroid therapy, laboratory tests, and biopsy in a limited number of cases.[92] There is a group of diverse disease entities that can mimic pseudotumors such as lymphoma, sarcoidosis, and other granulomatous diseases. By definition, the diagnosis excludes orbital inflammatory disease caused by entities such as Wegener's granulomatosis, retained foreign bodies, sclerosing hemangioma, trauma, and sinusitis. Among orbital disorders, after Graves' disease, pseudotumor is the next most common ophthalmologic disease. Pseudotumors account for 4.7% to 6.3% of orbital disorders, and the disease usually affects adults but may also affect children.[92] Pediatric orbital pseudotumor encompasses almost 6% to 16% of orbital pseudotumors. There is a higher incidence of bilateral orbital involvement, with approximately one third of the pseudotumors being bilateral.[92] Such pseudotumors are rarely associated with systemic disease. Children with orbital pseudotumor may also exhibit papillitis or iritis.[5, 6] Bilateral orbital pseudotumors in adults suggest the possibility of systemic vasculitis or a systemic lymphoproliferative disorder.[5, 6] Patients with pseudotumor typically present with the acute onset of orbital pain, restricted eye movement, diplopia, proptosis, and impaired vision from perioptic nerve involvement. Conjunctival vascular congestion and edema, as well as lid erythema and swelling, are common.[5, 6] Pseudotumors are often multicentric. In addition to the variety of classification systems and diagnostic criteria that have been offered over the years, the disease can include a wide range of clinical presentations and many of the symptoms are nonspecific. Pain is an important feature of pseudotumors; however, not all patients with pseudotumors present with pain.[5, 6] Some may have minimal proptosis or may even present with a totally scarred lesion (sclerosing pseudotumor) within a single muscle or in the retrobulbar fat pad.[5, 6]

Histopathology

The condition was first described in 1905 by Birch-Hirschfield[95] and has remained somewhat of an enigma in

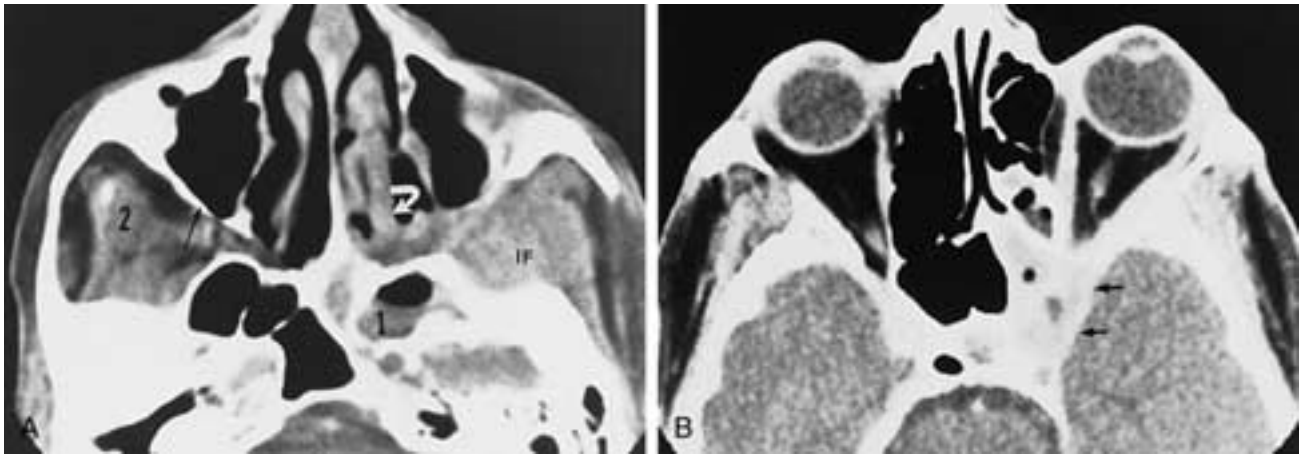

FIGURE 9-70 Mucormycosis. **A**, Axial CT scan shows soft-tissue induration in the left nasal cavity (*curved arrow*) and left infratemporal fossa (*IF*). Note the air-fluid level in the left sphenoid sinus (*1*). Fascial planes in the left infratemporal fossa (*IF*) region, compared with the right side (*2*), are obliterated. Note the rarefaction of the posterior wall of the left maxillary sinus compared with the normal right side (*black arrow*). **B**, Axial CT scan, same patient as in **A**, shows involvement of the left cavernous sinus (*arrows*) with enlargement (engorgement) of the left lateral and medial rectus muscles.

FIGURE 9-71 Aspergillosis. **A**, Axial T2-weighted MR image shows soft-tissue induration in the left sphenoid sinus (*white arrow*). Note the internal carotid (*C*) and early soft-tissue infiltration of the left cavernous sinus (*hollow arrow*). **B**, Axial PW MR image follow-up scan. **C**, Axial T2-weighted MR image follow-up scan. Scans show progression of the pathologic process, with marked infiltration of the left cavernous sinus (*C*) and formation of the left temporal lobe abscess (*arrowhead*) with marked peripheral edema. Note apical infiltration into the left orbit (*black arrow* in **B**) and inflammatory mycotic tissue in the left sphenoid sinus (*white arrow*). The mycotic process appears rather hypointense on the T2-weighted MR image, a not uncommon finding with fungal infections. Note the nonvisualization of the left internal carotid artery (compare with **A**); this results from invasion of the mycotic process, a finding confirmed by angiography and surgery. The mycotic process (*m*) has extended over the left petrous apex. **D**, Postcontrast (Gd-DTPA) coronal MR image shows enhancement of mucosal thickening of the left sphenoid sinus (*S*) and infiltrative process of the left cavernous sinus (*C*) and the temporal lobe abscess (*arrowhead*).

the ophthalmology, radiology, and pathology literatures.[94] The histopathology can vary from polymorphous inflammatory cells and fibrosis with a matrix of granulation tissue, eosinophils, plasma cells, histiocytes, lymphoid follicles with germinal centers and lymphocytes to a predominantly lymphocytic form (lymphoid hyperplasia) embedded in a loose fibrous stroma. It is the chronic lymphocytic variety that is related to lymphoma.[94] Many cases have been reported of lymphocytic pseudotumor that over a period of time are found to harbor a malignant lymphoma without any evidence of systemic lymphoma. The presence of germinal follicles and increased vascularity is indicative of a reactive lesion, often associated with a favorable prognosis and responsiveness to steroids. An association has been noted between diffusely distributed lymphoblasts, unresponsiveness to steroids, and a probable neoplastic lymphoid lesion.[94] However, not all steroid-resistant pseudotumors are destined to become lymphomatous. The peculiar behavior of pseudotumors has led some authors to speculate that some forms of pseudotumor are the result of an autoimmune

Copyright © 2003, Mosby, Inc. All rights reserved.

process.[94, 96] Pseudotumors are often multicentric, presenting with myositis, dacryoadenitis, sclerotenonitis (Tenon fasciitis), and inflammation of the dural sheath of the optic nerve and surrounding connective tissue.[5, 6] Pseudotumors may be classified as (1) acute and subacute idiopathic anterior orbital inflammation; (2) acute and subacute idiopathic diffuse orbital inflammation; (3) acute and subacute idiopathic myositic orbital inflammation; (4) acute and subacute idiopathic apical orbital inflammation; (5) idiopathic dacryoadenitis; and (6) perineuritis. Tolosa-Hunt syndrome (painful ophthalmoplegia) is a variant of pseudotumor in which the inflammatory process is restricted to the vicinity of the superior orbital fissure, the optic canal, or the cavernous sinus.[5, 6]

Anterior Orbital Inflammation

In the anterior orbital pseudotumor group, the main focus of inflammation involves the anterior orbit and adjacent globe.[3] The major features at presentation are pain, proptosis, lid swelling, and decreased vision. Other findings may be ocular and include uveitis, sclerotenonitis (Tenon's capsule), papillitis, and exudative retinal detachment. Extraocular muscle (EOM) motility is usually unaffected. CT and MR imaging show thickening of the uveal-scleral rim with obscuration of the optic nerve junction, which enhances with contrast infusion on CT (Fig. 9-72).[94] These findings are due to leakage of proteinaceous edema fluid into the interstitium of the uvea and Tenon's capsule secondary to the inflammatory reaction.[94] Fluid in Tenon's capsule has been well documented with ultrasound (the T sign). Patients with posterior scleritis can develop retinal detachment and fundal masses, which simulate intraocular tumors.[94] The differential clinical diagnosis of anterior orbital pseudotumor includes orbital cellulitis, ruptured dermoid cyst, or hemorrhage within a vascular lesion (hemangioma, lymphangioma), collagen vascular disease, rhabdomyosarcoma, and leukemic infiltration.

Diffuse Orbital Pseudotumor

Diffuse orbital pseudotumor is similar in many respects to acute and subacute anterior inflammation, with more severe signs and symptoms.[3] The diffuse, tumefactive, or infiltrative type of pseudotumor may fill the entire retrobulbar space and mold itself around the globe while respecting its natural shape. Even the largest mass usually does not invade or distort the shape of the globe or erode bone (Figs. 9-73 and 9-74). This type of disease can be very difficult to differentiate from lymphoma. These large, bulky masses can be intraconal, extraconal, or involve both spaces. This disease must be differentiated from true tumors of the orbit such as cavernous hemangioma, hemangiopericytoma, optic nerve sheath meningioma, optic nerve glioma, orbital schwannoma, and metastasis.[94] True tumors usually do not respect the boundaries of the globe, indenting or deforming its surface. Also, bone erosion and extraorbital extension are more typical of true tumors than of pseudotumors.

Orbital Myositis

Idiopathic orbital myositis is a condition in which one or more of the EOMs are primarily infiltrated by an inflammatory process (Figs. 9-75 to 9-79). The myositis can be acute, subacute, or recurrent, and the patient usually presents with painful extraocular movements, diplopia, proptosis, swelling of the lid, conjunctival chemosis, and inflammation over the involved EOM.[3, 94] This disorder may be bilateral. The most frequently affected muscles are the superior complex and the medial rectus (Fig. 9-75). The major differential diagnosis is Graves' disease. However, dysthyroid myopathy is usually painless in onset, asymmetric, slowly progressive, and associated with a systemic diathesis.[3] Trokel and Hilal state that the typical CT finding in orbital myositis is enlargement of the EOMs, which extends anteriorly to involve the tendon insertion (Figs. 9-75 and 9-76).[97] Other helpful indicators of inflammatory orbital myositis include a ragged, fluffy border of the involved muscle, with infiltration and obliteration of the fat in the peripheral surgical space between the periosteum of the orbital wall and the muscle cone. Also observed is an inward bowing of the medial contour of the muscle belly, forming a shoulder as it passes behind the globe (Fig. 9-75). All these findings can be attributed to local tendinitis, fasciitis, and

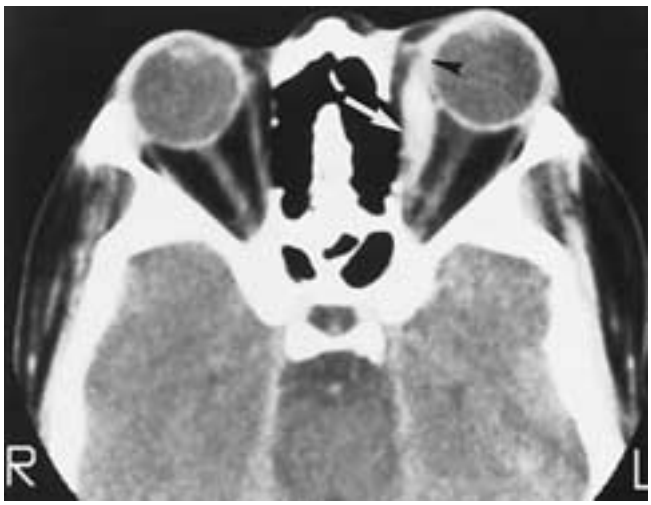
VIEW IMAGE

FIGURE 9-74 Pseudotumor. **A**, Axial PW MR image. **B**, Axial T2-weighted MR image. Scans show infiltrative process (*arrows*) compatible with pseudotumor. The lesion is isointense to brain on PW and T2-weighted MR scans. (From Curtin HD. Pseudotumor. Radiol Clin North Am 1987;25:583.)

myositis of the involved muscle. In contrast, the fusiform appearance of an enlarged muscle in thyroid myopathy is produced by a myositis without involvement of the muscle tendon insertion. The muscle borders are sharply defined, the fat in the peripheral surgical space is preserved, and there is no medial muscle bowing. Less common causes of EOM enlargement include arteriovenous fistula (e.g., carotid-cavernous fistula), granulomatous disease, and neoplasm (primary or metastatic).[94]

Perineuritis and Periscleritis

Idiopathic perineuritis (inflammation of the sheath of the optic nerve) can simulate optic neuritis by presenting with orbital pain, pain with extraocular motility, decreased visual acuity, and disc edema. In contrast to optic neuritis, pain is exacerbated with retrodisplacement of the globe, and there is mild proptosis.[94] CT and MR imaging show a ragged, edematous enlargement of the optic nerve sheath complex (Fig. 9-79A). If periscleritis is present, the inflammation involves the tissues immediately contiguous to the sclera (Fig. 9-79B).



VIEW IMAGE

FIGURE 9-75 Myositic pseudotumor. Postcontrast Axial CT scan shows marked thickening and enhancement of the left medial rectus muscle (*arrow*). Note extension of the process into its tendinous insertion on the globe (*arrowhead*). (From Flanders AE et al. CT characteristics of orbital pseudotumor and other orbital inflammatory processes. J Comput Assist Tomogr 1989;13:40–47.)

Lacrimal Adenitis

Acute idiopathic lacrimal adenitis (pseudotumor) presents with tenderness in the upper outer quadrant of the orbit in the region of the lacrimal gland.[24, 94] Viral dacryoadenitis may present in a similar manner, although it is commonly associated with an etiology such as mumps, mononucleosis, or herpes zoster virus infection. Adenopathy and lymphocytosis can be present in these latter cases. The differential diagnosis of nonspecific lacrimal adenitis includes viral and bacterial dacryoadenitis, rupture of a dermoid cyst in the lacrimal gland region, specific lacrimal gland inflammations such as sarcoidosis and Sjogren's disease, lymphoproliferative disorders, cysts, and neoplasia in this region. Because of the wide variety and incidence of pathology that can involve the lacrimal gland, biopsy of this accessible site is necessary to obtain a definitive diagnosis (Fig. 9-80).[3]

Apical Orbital Inflammation

Pseudotumor may present with infiltration of the orbital apex, and these patients present with a typical orbital apex syndrome consisting of pain, minimal proptosis, and painful ophthalmoplegia. The CT and MR imaging findings include an irregular infiltrative process of the orbital apex with extension along the posterior portion of the EOMs or the optic nerve. Sarcoidosis (Fig. 9-81) and other granulomatous processes including Wegener's granulomatosis may be responsible for similar clinical and imaging presentations.

Painful External Ophthalmoplegia (Tolosa-Hunt Syndrome)

In 1954, Tolosa described a patient with unilateral recurrent painful ophthalmoplegia involving cranial nerves III, IV, VI, and V1.[98] Carotid arteriography in this case

Copyright © 2003, Mosby, Inc. All rights reserved.

showed segmental narrowing in the carotid siphon. The patient died after surgical exploration, and a postmortem study showed adventitial thickening in the cavernous carotid artery surrounded by a cuff of nonspecific granulation tissue that also involved the adjoining cranial nerve trunks. In 1961, Hunt et al. reported six patients, with similar clinical symptoms and signs.[99] After reviewing Tolosa's slides, these authors proposed a low-grade, nonspecific inflammation of the cavernous sinus and its walls as the cause of the syndrome. They also emphasized that angiography was essential to rule out an aneurysm or neoplasm.[99] In 1966, Smith and Taxdal applied the term *Tolosa-Hunt syndrome* to this entity.[100] They described five additional cases and stressed the diagnostic usefulness of the dramatically rapid therapeutic response to corticosteroids. In 1973, Sondheimer and Knapp reported three patients with Tolosa-Hunt syndrome on whom orbital venography was performed.[101] These investigators observed that the superior ophthalmic vein on the affected side was occluded in the posterior portion of the muscle cone in each case and that there was partial or complete obliteration of the ipsilateral cavernous sinus.

Painful external ophthalmoplegia, or Tolosa-Hunt syndrome, is now considered an idiopathic inflammatory process and a regional variant of idiopathic orbital pseudotumors that, because of its anatomic location (superior orbital fissure, cavernous sinus, or both), produces typical clinical manifestations.[98, 102] The disease manifests as recurrent attacks of a steady, dull, retroorbital pain, palsies of the third, fourth, or sixth cranial nerve and the first or second divisions or both of the trigeminal nerve, and venous engorgement. It is usually unilateral, but bilateral cases do

occur.[92] Immediate relief of symptoms following high doses of steroid therapy differentiate pseudotumor of the orbital apex and cavernous sinus from other lesions causing a superior orbital fissure syndrome.

Pathologically there is an infiltration of lymphocytes and plasma cells along with thickening of the dura matter, and it is important to exclude the possibility of a neoplastic (Fig. 9-82A), inflammatory (particularly mycotic) (Figs. 9-70 and 9-71), or vasogenic lesion. Carotid angiography and MR imaging are most useful in excluding an aneurysm as a cause of the clinical signs and symptoms.[103] Certain cavernous sinus, orbital apex, and parasellar lesions such as lymphoma, including Burkitt's lymphoma, leukemic infiltration, granulomatous diseases, pituitary adenomas, meningiomas, craniopharyngiomas, neurogenic tumors, dermoid cysts, orbital/sinonasal and nasopharyngeal carcinomas, invasive mycotic infections, aneurysm, and metastatic lesions (melanoma, lung, breast, kidney, thyroid, and prostate cancers) may produce similar symptoms.[103]

Thyroid Orbitopathy (Graves' Dysthyroid Ophthalmopathy)

Thyroid orbitopathy, or Graves' dysthyroid ophthalmopathy, is the most common cause of unilateral and bilateral exophthalmos in the adult population.[6, 103] The disease usually has its onset between the ages of 20 and 45 years.[6] The mean age of presentation for Graves' thyroid disease is 41 years, and the orbital disease occurs, on average, 2 to 5 years afterward.[104] Even though the disease is more common in women, its severity tends to be greater in men and in patients more than 50 years of age.[104] Graves' disease is a multisystem disease of unknown cause characterized by one or more of the three pathognomonic clinical entities: (1) hyperthyroidism associated with diffuse hyperplasia of the thyroid gland; (2) infiltrative ophthalmopathy; and (3) infiltrative dermopathy.[6] Thyroid orbitopathy (Graves' disease) includes any of the orbital and eyelid manifestations of this disorder. Among these clinical features are upper and lower eyelid retraction, exophthalmos, limitation of eye movements, eyelid edema, and epibulbar vascular congestion.[6] Although the majority of patients with thyroid orbitopathy have hyperthyroidism, the orbital manifestations of the disease may occur in individuals who are hypothyroid or euthyroid.[6] Occasionally, Graves' ophthalmopathy occurs in patients with Hashimoto's thyroiditis.[103]

Pathology

Immunopathology

Thyroid orbitopathy is presumed to be an autoimmune disease.[6, 103] It is postulated that the immune complexes (thyroglobulin and antithyroglobulin) reach the orbit via the superior cervical lymph channels that drain both the thyroid and the orbit.[6] These complexes bind to extraocular muscles and stimulate acute inflammation characterized by an influx of lymphocytes, plasma cells, mast cells, and fibroblast proliferation, glycosaminoglycan overproduction, and orbital congestions.[6, 103, 104] Circulating autoantibodies against a human eye muscle-soluble antigen have been detected in a significant percentage of patients with thyroid orbitopathy, and both humoral and cell-mediated immune mechanisms have been implicated.[6, 103] Immunohistochemical analysis and histologic findings have shown orbital infiltration with mononuclear cells sensitized to retro-orbital antigens.[103] Cytokines released by the infiltrating monocytes may stimulate immunomodulatory protein expression,

Copyright © 2003, Mosby, Inc. All rights reserved.

glycosaminoglycan production, and proliferative activity from orbital fibroblasts.

Histopathology

Generally, as in other forms of inflammatory myositis, the histopathology in Graves' ophthalmopathy consists early on of inflammatory cell infiltration, mucopolysaccharide deposition, and increased water content.[103] The EOMs are infiltrated by lymphocytes and contain an increased amount of hyaluronic acid, which binds to water and accounts for some of the orbital congestion.[6] In the chronic stage of the disease, the EOMs undergo degeneration of the muscle fibers and replacement fibrosis.[6, 103] Restrictive myopathy is caused by this fibrosis.

Diagnosis

The diagnosis of thyroid orbitopathy is based primarily on the patients' symptoms and clinical findings. Laboratory testing, including imaging studies, often is valuable in confirming the diagnosis.[6] The active phase of inflammation and progression tends to stabilize spontaneously 8 to 36 months after onset.[103] Exophthalmos, lid retraction, lid lag, prominence of the episcleral vessels, and lid edema are important clinical findings. In some patients, the disease is characterized by the gradual onset of primarily verical gaze diplopia.[11] In patients with Graves' ophthalmopathy, the forced duction test result is almost always abnormal, and limitation is the most common disturbance of ocular motility.[11, 14] The exophthalmos is the result of enlargement of the EOMs and/or increased orbital fat volume.[103] The exophthalmos is almost always bilateral and usually relatively symmetric, although occasionally it may be quite asymmetric.[103] The inferior rectus muscle is involved most commonly, followed by the medial rectus and the superior rectus.[103]

Diagnostic Imaging

CT and MR imaging in the acute congestive phase may show only markedly swollen retrobulbar orbital contents causing bilateral proptosis. The muscle bellies need not be

Radiol Clin North Am 1999;37:73–87.)

enlarged. However, in this early stage of the disease, there also may be enlargement of the EOMs, and the coronal view is especially valuable in evaluating the degree of muscle enlargement and any optic nerve compression at the orbital apex. The increased orbital fatty reticulum results in anterior displacement of the orbital septum and at times prolapse of lacrimal glands. Strangulation of the optic nerve is seen best on axial CT scans.[3, 11]

About 90% of patients with thyroid orbitopathy have bilateral CT or MR imaging abnormalities (Figs. 9-83 and 9-84), even if the clinical involvement is unilateral.[3] Typically, enlargement involves the muscle belly, sparing the anterior tendinous insertion. However, there are rare patients who show thickening of the tendinous portion of the muscle.[3] Another helpful finding in thyroid myopathy is the presence of low-density areas within the muscle bellies. These are probably the result of focal accumulation of lymphocytes and mucopolysaccharide deposition.[3] Other CT and MR imaging findings in thyroid orbitopathy are increased orbital fat, enlargement (engorgement) of the lacrimal glands, edema (fullness) of the eyelids, proptosis, anterior displacement of the orbital septum, and stretching of the optic nerve with or without associated ''tenting'' of the posterior globe. On T2-weighted MR images, areas of high signal intensity may be present within the involved muscle. These areas presumably represent inflammation, and it is in these patients that a good clinical response to a trial of steroid therapy occurs. Later, a more chronic noncongestive phase follows, in which a restrictive type of limited eye movement often develops, secondary to fibrosis of the EOMs and to subsequent loss of elasticity.[11] At this stage, CT and MR imaging may show fatty replacement of the EOMs (Fig. 9-84B) or a string-like appearance of the EOMs (Fig. 9-84C). Although the muscles may be moderately to markedly attenuated, the orbital fatty reticulum volume remains increased, as may be evidenced by exophthalmos, anterior displacement of the orbital septum, and prolapse of the lacrimal glands. The differential diagnosis of Graves' dysthyroid orbitopathy on a clinical basis includes tumors that may be primary or metastatic, orbital inflammation including pseudotumor, and carotid cavernous or dural shunt fistulas. All of these conditions can usually be distinguished from Graves' orbitopathy on CT or MR images. However, at times, orbital myositis secondary to an inflammatory sinusitis, trichinosis, or a myositis due to

systemic diseases such as Crohn's disease or Wegener's granulomatosis, pseudotumor, lymphoma, and even metastases to extraocular muscles may be difficult to differentiate on imaging studies.

Sarcoidosis

Sarcoidosis is a granulomatous systemic disease that occurs worldwide, affecting persons of all races, both sexes, and all ages. It has a particular proclivity for adults under the age of 40 and for certain ethnic and racial groups. Estimates of the prevalence of sarcoidosis range from fewer than 1 to 40 cases per 100,000 population, with an age-adjusted annual incidence rate in the United States of 10.9 per 100,000 for whites and 35.5 per 100,000 for African Americans.[105] Higher annual incidence rates have been reported in other studies among African Americans, Irish, and Scandinavians. Sarcoidosis affects African Americans more acutely and more severely than it does people of other races. The cause of sarcoidosis remains obscure. The diagnosis of sarcoidosis is generally based on a biopsy finding of noncaseating granulomas with no other explanation.[3, 105]

The presenting features of sarcoidosis are protean, ranging from asymptomatic with abnormal findings on chest radiography in many patients to progressive multiorgan failure. Ophthalmic lesions develop in approximately 25% of patients, and virtually any part of the globe or orbit may be involved. There may be uveitis, chorioretinitis, and keratoconjunctivitis, and conjunctival inflammatory nodules may be seen.[3] The most common form of orbital involvement in sarcoidosis is chronic dacryoadenitis. This may be unilateral and may easily mimic a lacrimal gland tumor (Fig. 9-85A). Involvement of the lacrimal glands may also be very extensive (Fig. 9-85B), and when it occurs bilaterally in the lacrimal and salivary glands, it causes a Mikulicz-like syndrome of dry eyes and xerostomia.[17, 105] Sarcoid may also involve the optic nerve, and when this occurs, it may clinically resemble a primary neoplasm of the optic nerve (Fig. 9-86).[106, 107]

The classic symptoms of anterior uveitis have a rapid onset, with blurred vision, photophobia, and excessive lacrimation. These symptoms usually clear spontaneously within a year. Sarcoidosis may affect virtually any part of the nervous system. Among the 5% of patients so affected, involvement of the facial nerve is the most common and bilateral facial nerve palsy should be considered highly suspicious for sarcoidosis or Lyme disease. Any cranial nerve can be affected. The most common cranial nerves to be affected are the optic nerve, facial nerve, trigeminal nerve, acoustic nerve, oculomotor nerve, and abducens nerve in decreasing order of involvement. The illness can be self-limited or chronic, with episodic recrudescence and remissions.

It is not clear why some patients recover spontaneously, whereas others worsen. Visual system abnormalities are the most common extrathoracic manifestations of sarcoidosis. In addition to the globe, the conjunctiva, EOMs, retrobulbar space, lacrimal gland, optic nerve, chiasm, and optic radiations (meningovascular infiltration) may be affected.[105] These patients may present with confusing clinical and radiologic findings, especially if ophthalmic and neurologic involvement precedes systemic symptoms. Several investigators have characterized the MR imaging findings in neurosarcoidosis and in orbital and optic pathway sarcoidosis.

Pathologic and Immunologic Features

Sarcoidosis is a disorder mediated by excess helper T-lymphocyte activity at sites of disease activity. The noncaseating granulomas consist of mononuclear inflammatory cells, histiocytes, lymphocytes, plasma cells, and multinucleated giant cells.[105] Some of the granulomas may

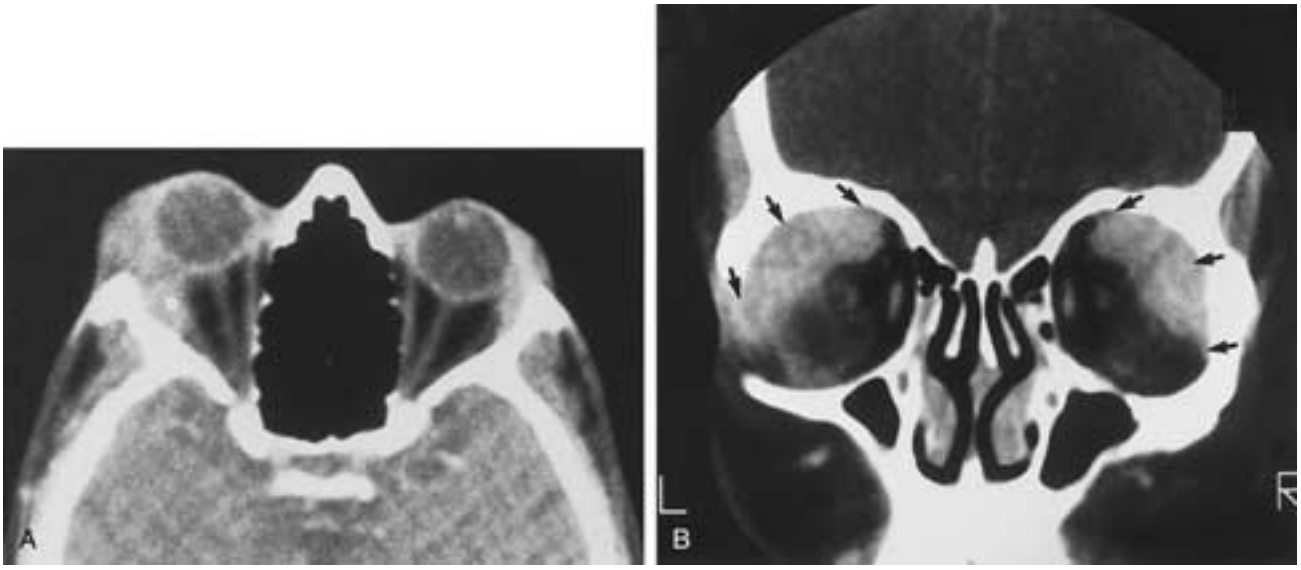

FIGURE 9-85 **A**, Sarcoidosis chronic dacryoadenitis. Axial CT scan shows enlargement of the right lacrimal gland. Note the mild enlargement of the left lacrimal gland. **B**, Sarcoidosis. Coronal-enhanced CT scan shows moderate enhancement of markedly enlarged lacrimal glands (*arrows*).

have necrotic centers. Once mononuclear inflammatory cells accumulate in the target organ, macrophages aggregate and differentiate into epithelioid and multinucleated giant cells. Significant CD4 (helper-inducer) T cells are interspersed among these inflammatory cells. In time, CD4 and CD8 lymphocytes, and to a lesser extent B lymphocytes, form a rim around the granuloma. Except in the earliest stages of the granuloma, a dense band of fibroblasts, mast cells, collagen fibers, and proteoglycans begins to encase the cluster of cells in the granuloma. Fibrosis is an unfortunate outcome for many patients with sarcoidosis. Macrophages have a critical role in inducing fibroblasts to proliferate and to produce fibronectin and collagen in the lung. Most cells also contribute to the chronic fibrotic response in the granulomas.

Clinical Features

The clinical presentation of sarcoidosis may range from widespread disease to involvement of only one organ system at a time. Many asymptomatic cases are discovered during screening chest radiography, and these patients may or may not progress to clinically symptomatic disease. The majority of patients, however, present with systemic symptoms. In the United States, more than 50% of patients present with chronic respiratory symptoms and few constitutional symptoms. Lofgren's syndrome is referred to as the *constellation*

Copyright © 2003, Mosby, Inc. All rights reserved.

of erythema nodosum, bilateral hilar adenopathy, and *polyarthralgias*. Uveitis and parotiditis are referred to as *uveoparotid fever* or *Heerfordt's syndrome*. Lupus pernio is referred to as *nasal sarcoidosis*.[105]

There are no definitive diagnostic blood, skin, or radiologic imaging tests specific for the disorder. Although an elevated angiotensin converting enzyme (ACE) level helps to establish a diagnosis of sarcoidosis, measurement of serum ACE activity and gallium-67 scanning add little diagnostic value because of their lack of specificity.[105] Oksanen reviewed 50 cases of neurosarcoidosis and found that the ACE in the CSF was elevated in 18 of the 31 patients in whom it was measured.[105] The Kveim-Siltbach skin test is not widely available and is not approved for general use by the Food and Drug Administration. Respiratory tract involvement occurs at some time in the course of nearly all cases of sarcoidosis. Pulmonary involvement in sarcoidosis is typically bilateral, with four radiographic patterns: (1) bilateral lymphadenopathy without parenchymal abnormalities; (2) bilateral hilar lymphadenopathy with diffuse parenchymal changes; (3) diffuse parenchymal changes without hilar lymphadenopathy; and (4) diffuse parenchymal changes without hilar lymphadenopathy with upper lobe retraction. Hilar adenopathy is frequently accompanied by right paratracheal lymphadenopathy. Atypical radiographic presentations include unilateral lung or lobar infiltrates, unilateral lymphadenopathy, and predominant upper lobe involvement.[105]

Intrathoracic and peripheral lymphadenopathy are common, with radiographic evidence of hilar node enlargement in up to 90% of patients. Peripheral lymphadenopathies are typically nontender. Approximately 25% of patients have one or more skin manifestations. Dermatologists frequently detect sarcoidosis during a biopsy of atypical skin lesions. Lupus pernio produces indurated violaceous lesions principally on the cheeks, nose, lips, and ears.[105]

As mentioned, the ophthalmic lesions include uveitis (Fig. 9-87), infiltration of the lids, optic nerve (Fig. 9-88), orbit and EOMs (Fig. 9-81), granulomatous infiltration of lacrimal glands (Figs. 9-89 and 9-90), retinal vasculitis, uveitis, uveoretinitis, and vitritis. Dykhuizen and associates[108] reported a case of sarcoidosis that presented with recurrent headaches, transient right hemiparesis, and left-sided ophthalmoplegia. An excised left retrobulbar lesion demon-

strated sarcoid granulomatosis. Twelve years later, the patient developed a mass in the right lung. The excised lung mass was similar histologically to the previously removed left orbital mass. Idiopathic orbital inflammation displays a granulomatous inflammatory pattern that may mimic sarcoidosis. Raskin and associates[109] reported 12 patients with a diagnosis of sarcoidosis or another noninfectious granulomatous process involving the orbit. Five of these patients were diagnosed with sarcoidosis on histologic examination. In these patients, evaluation failed to reveal evidence of systemic involvement. The authors suggested that the clinicians should be aware of the existence of granulomatous idiopathic orbital inflammation not associated with systemic sarcoidosis as a distinct clinicopathologic entity. Monfort-Gouraud and associates[110] reported an inflammatory pseudotumor of the orbit and suspected sarcoidosis in a 13-year-old boy who had uveitis and symptoms of unilateral orbital inflammation. Mombaerts and associates[111] reported seven patients with unilateral idiopathic granulomatous orbital inflammation. Histopathologic analysis showed a spectrum of granulomatous inflammation admixed with nongranulomatous inflammation and fibrosis. They concluded that based on their study and review of the literature,

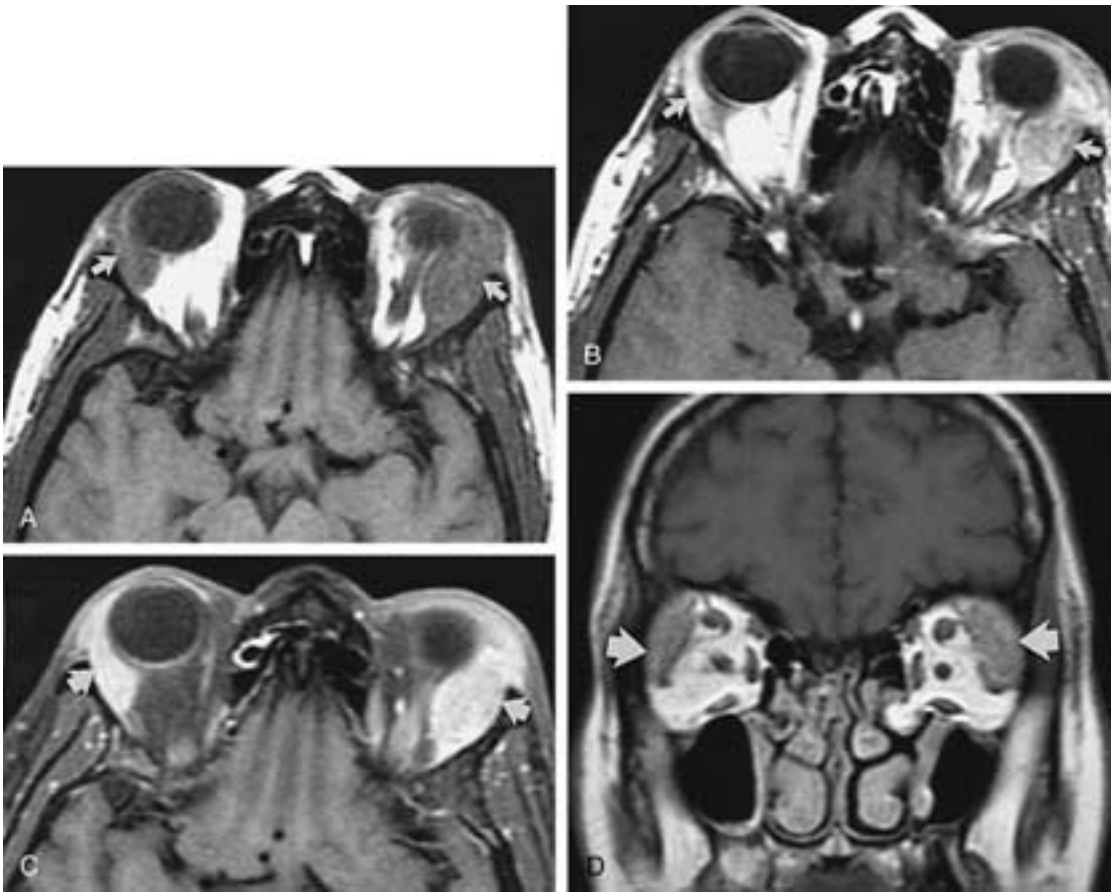

FIGURE 9-90 Sarcoidosis of lacrimal gland. Unenhanced, axial, T1-weighted (500/17, TR/TE) (**A**), enhanced, axial, T1-weighted (500/17, TR/TE) (**B**), enhanced, axial, fat-suppressed T1-weighted (500/17, TR/TE) (**C**), and enhanced, coronal, T1-weighted (600/18, TR/TE) (**D**) MR images show enlargement as well as increased enhancement of both lacrimal glands (*arrows*), more so on the left side. it appears that idiopathic granulomatous orbital inflammation is more closely related to orbital pseudotumor than to orbital sarcoidosis.

Carmody et al.[112] reported the MR imaging scans of 15 patients, 3 with presumed and 12 with proven orbital or optic pathway sarcoidosis. Eight patients had MR imaging evidence of optic nerve involvement by sarcoid granuloma. Perineural enhancement was seen in four cases and optic atrophy in one. Nine patients had optic chiasmal involvement. One patient had increased T2-weighted signal intensity in the optic radiations. Three patients had orbital masses that had MR imaging signal characteristics similar to those of idiopathic pseudotumor. Five patients had periventricular white matter abnormalities closely resembling multiple sclerosis.

Recently, Ing et al.[113] reported a 22-year-old white woman with optic nerve sarcoidosis without evidence of systemic or ocular disease. The authors found 17 cases similar to hers, with the diagnosis proved by optic nerve biopsy, reported in the English-language literature. In all of them, extensive prospective investigations revealed no systemic sarcoidosis. Most of these cases were initially mistaken for optic nerve sheath meningioma.

Neurosarcoidosis may produce anosmia and is frequently associated with ocular findings. In many cases of neurosarcoidosis, a diagnosis of meningioma is suspected preoperatively. Hypothalamic involvement in sarcoidosis is not uncommon and may mimic hypothalamic glioma. Lymphoma and Castleman's disease may involve the central nervous system including leptomeninges mimicking neurosarcoidosis and meningioma. Lymphoma may have primary intraorbital, intraocular, and intracranial involvement. Involvement of the optic nerve and other cranial nerves by angiocentric T-cell lymphoma, also known as *lymphomatoid granulomatosis*, has been reported.[105] Castleman's disease, a benign lymphoproliferative disorder related to lymphoma, is characterized by hyperplastic lymphoid follicles with capillary proliferation. This disorder was initially observed by Castleman in the mediastinum, but later reports described involvement elsewhere, including orbital and intracranial involvement.

Neurologic involvement with sarcoidosis takes two forms. In acute sarcoidosis, there tends to be involvement of a peripheral nerve, especially a cranial nerve and in particular the facial nerve. The optic nerve (which is not a peripheral nerve) is involved next most frequently. As mentioned, sarcoid uveitis in combination with a facial nerve palsy and fever is known as *Heerfordt's syndrome* or *uveoparotid fever*. The second form of nervous system sarcoidosis occurs in the chronic form of the disease with central nervous system involvement. Involvement of the optic nerve is more common in this form.[105] The involvement may be at the chiasm or in the intracanalicular or intraorbital segments of the optic nerve. Optic neuritis, granulomatous protrusions from the optic nerve head into the vitreous, and optic atrophy are manifestations of central nervous system and optic nerve sarcoid disease. Apart from the involvement of the lacrimal gland, involvement of the orbital tissues by true systemic sarcoidosis is rare.

Orbital pseudotumor may have a granulomatous pattern, which can easily be mistaken for sarcoidosis. Sarcoidosis-like lesions can be found in patients with syphilis, lymphogranuloma venereum, leprosy, tularemia, torulosis, histoplasmosis, blastomycosis, and coccidioidomycosis. The early lesions of sarcoidosis are much more likely to respond to corticosteroid therapy than are the late, fibrotic, hyalinized lesions. Lesions that demand systemic corticosteroid therapy are uveitis, optic neuritis, diffuse pulmonary and central nervous system lesions, persistent facial palsy, persistent hypercalcemia, and cutaneous lesions.

Optic Nerve Sarcoidosis

Certain inflammatory conditions, such as syphilis, tuberculosis, or sarcoidosis, may be responsible for a chronic and progressive loss of vision. Chronic optic neuropathy, however, is more frequently due to a compressive lesion, such as meningioma (intracanalicular, intraorbital, or tuberculum sellae), pituitary tumor, or paraclinoid aneurysm. Sarcoidosis frequently involves the nervous system and can present as an abrupt or chronic visual loss, with or without disc changes. In one series of 11 cases of sarcoidosis of the optic nerve in patients ranging in age from 16 to 48 years, only two patients were previously known to have the disorder.[114] Four patients showed disc granulomas, four had optic nerve granulomas, and five had posterior uveitis and retinitis. In this series, chest radiographs were characteristically abnormal in 8 of the 11 patients.[114] Only one third had elevated serum levels of ACE. CT scans in these 11 patients infrequently showed enlarged nerves or other findings. Although sarcoidosis is classically believed to commonly not involve the optic nerves, increasing numbers of cases of presumed optic nerve sarcoidosis have been seen on MR images and CT scans, some of them with histologic confirmation. Although neuroimaging does not distinguish optic nerve sheath meningioma from sarcoid of the optic nerve, in the absence of uveitis and systemic sarcoid disease certain imaging features should raise the possibility of optic nerve sarcoidosis, prompting a trial of corticosteroid therapy before proceeding to biopsy. Imaging features that may favor a diagnosis of sarcoidosis of the optic nerve include (1) enhancement of the optic nerve associated with prominent enlargement of the intracranial segment of this nerve; (2) enlargement of the intracranial segment of the optic nerve associated with contrast enhancement; and (3) abnormal enhancement of the optic nerve associated with abnormal dural and leptomeningeal enhancement. Bilateral optic nerve enlargement along with abnormal enhancement has not been seen. This finding should favor optic nerve sheath meningioma, demyelinating disease, optic glioma, lymphoma, leukemic infiltration, or pseudotumor. Optic nerve sarcoidosis in persons under age 16 years is extremely rare.[105] Enlargement and enhancement of the optic nerve in children is seen with optic nerve glioma, extension of retinoblastoma along the optic nerve, leukemic infiltration, and in very rare cases of optic nerve sheath meningioma and optic nerve medulloepithelioma.[105]

Diagnostic Imaging in Optic Nerve Sarcoidosis

When an ophthalmologist or neurologist suspects that an optic nerve is involved by sarcoidosis or that there is sarcoid of the central nervous system, a chest radiograph can be very useful. Active pulmonary sarcoidosis characteristically shows bilateral hilar adenopathy, with or without parenchymal disease. The nodes characteristically stand out from the

Copyright © 2003, Mosby, Inc. All rights reserved.

right heart border, and there is associated right paratracheal nodal involvement. Chest abnormalities are found in about 80% of patients with ocular sarcoidosis (uveitis). Gallium scintigraphy is more sensitive than chest radiography for showing pulmonary involvement in patients with sarcoidosis.[105] It lacks specificity, however, because other pulmonary diseases also show similar uptake. Lacrimal gland uptake of gallium-67 also occurs in more than 80% of patients with active sarcoidosis. This uptake is also nonspecific.[105]

In patients with ocular, orbital, and optic nerve sarcoidosis as well as neurosarcoidosis, MR imaging remains the imaging study of choice. Gadolinium-enhanced T1-weighted pulse sequences are the most informative part of the MR imaging study (Fig. 9-88), and enhanced fat-suppressed, T1-weighted MR images are essential for the diagnosis of optic nerve sarcoidosis or simulating lesions.[105]

Sjogren's Syndrome

Sjogren's syndrome is an autoimmune disorder characterized by keratoconjunctivitis sicca and xerostomia. Patients may have an associated autoimmune disease such as rheumatoid arthritis, systemic lupus erythematosus, polymyositis, scleroderma, or vasculitis. The lacrimal and salivary glands are initially infiltrated by periductal lymphocytes, and eventually atrophy of the acini with hyalinization and fibrosis occurs. The early disappearance of lysozymes from the tears in Sjogren's syndrome may help distinguish it from sarcoidosis, a disease in which the lysosomes in the tears are actually increased.

Vasculitides (Angiitides)

The vasculitides are an immunologically complex-mediated group of diseases that include a variety of inflammatory angiodestructive processes. Clinically, the vasculitides may show features of acute, subacute, and chronic inflammatory and vaso-obstructive signs and symptoms.[3] This group of diseases includes a wide variety of disorders that are usually classified on the basis of the symptoms they produce and the organs affected, as well as their histopathologic features.[3] The major ophthalmic or orbital diseases include polyarteritis nodosa, Wegener's granulomatosis, T-cell or B-cell lymphoma (previously called *idiopathic midline destructive disease*, *malignant midline reticulosis*, or *polymorphic reticulosis*), giant cell arteritis (temporal arteritis), hypersensitivity (leukocytoclastic) angiitis, and connective tissue disease, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and polymyositis.

Wegener's Granulomatosis

Wegener's granulomatosis is a multisystem disease characterized by a triad of necrotizing granulomas in the upper and lower respiratory tracts, necrotizing vasculitis (focal necrotizing angiitis of small arteries and veins) of the lung, upper respiratory tract, and other sites, and glomerulonephritis.[3, 107] If left untreated, the disease is often fatal. The introduction of combined corticosteroid cyclophosphamide treatment has proven very successful.[3] The main chronic inflammatory or granulomatous processes that involve the sinus and the orbit include Wegener's granulomatosis and sarcoidosis.[102] Wegener's granulomatosis often mimics inflammatory, infectious, or malignant diseases and clinically involves the respiratory tract and kidneys.[102] However, ocular involvement is also common, occurring in 18% to 50% of the cases.[102] The disease may cause scleritis, episcleritis, uveitis, retinal vasculitis, and, rarely, conjunctival involvement. The condition is characterized by pain, proptosis, motility disturbance, chemosis, papilledema, and erythematous edema of the eyelids.[3, 107] Characteristically, ocular and orbital involvement is bilateral and either nonresponsive or transiently responsive to corticosteroids, often providing a clue to the diagnosis.[3] Involvement of the ocular adnexa includes lacrimal gland enlargement, nasolacrimal obstruction, and eyelid fistula formation.[3] The disease most commonly spreads from the paranasal sinuses to the orbit and produces pain, ophthalmoplegia, and loss of vision.[102] Although Wegener's granulomatosis characteristically occurs in the fifth decade of life, it has been documented in children.[102]

Orbital involvement with Wegener's granulomatosis should be differentiated from idiopathic pseudotumors, lymphoreticular proliferative disorders, and metastatic carcinoma.[107] The CT and MR imaging appearance of Wegener's granulomatosis is similar to that of pseudotumor and lymphoma (Figs. 9-91 and 9-92), and nasal and paranasal sinus involvement is present in the majority of cases (Fig. 9-82A). These diseases are definitively differentiated by biopsy, and a high titer of serum antineutrophil cytoplasmic antibodies is highly indicative of Wegener's granulomatosis. Treatment of the disease with glucocorticoids and cyclophosphamide results in complete remission in 75% of patients and partial remission in another 15%.[109]

B-Cell and T-Cell Lymphoma[109]

B-cell or T-cell lymphoma was formerly referred to as *idiopathic midline destructive disease*, *lethal midline granuloma*, *malignant midline reticulosis*, and *polymorphic reticulosis*. This disease is a clinical entity characterized by extensive destructive lesions of the nose, paranasal sinuses, and pharynx, often with associated involvement of the orbit and central facial bones. It has some similarity to Wegener's granulomatosis, but pulmonary disease is rare and renal involvement is absent.[107] This disease, which is not necessarily midline,[102, 115] is characterized by progressive unrelenting ulceration and necrosis, with destruction of the nasal septum. Most of these tumors are classified as T-cell lymphomas and are associated with Epstein-Barr virus infection.[102, 115] If the biopsy result indicates granulomatous vasculitis, the preferred treatment is cyclophosphamide and corticosteroids, as used for Wegener's granulomatosis. If the biopsy shows a lymphomatous process, radiotherapy is considered the treatment of choice.[107]

Periarteritis Nodosa (Polyarteritis Nodosa)

This condition is a vasculitis of the medium-sized and small arteries, adjacent veins, and occasionally arterioles and venules. The disease is segmental and leads to nodular aneurysms. The major ophthalmologic manifestations are retinal and choroidal infarcts that lead to exudative retinal

detachment. Proptosis may occur secondary to severe inflammation of the orbital arteries, often leading to necrosis of the orbital connective tissues.[3, 107]

Hypersensitivity (Leukocytoclastic) Angiitis

This condition resembles periarteritis nodosa microscopically, but it affects smaller vessels. Pathologically, the arterioles, venules, and capillaries are usually but not necessarily necrotic, or they may simply have perivascular infiltration, with neutrophils undergoing karyolysis (leukocytoclasis). The spectrum of clinical disease varies from widespread multisystem involvement to primary dermatologic lesions.[3]

Lupus Erythematosus

Any of the connective tissue disorders may be associated with systemic vasculitis. The most common ones include systemic lupus erythematosus, rheumatoid arthritis, and dermatomyositis. Systemic lupus erythematosus is an autoimmune disease that affects many organs. It has a female/male ratio of 9:1 and occurs primarily in the second and third decades of life.[3] Histologically, the vasculitides in the connective tissue diseases resemble hypersensitivity angiitis.[3]

Evidence of antinuclear antibodies is universally present in this disorder. Of these patients, 20% have ocular involvement, primarily affecting the retinal vessels.[3] Orbital involvement is rare and is believed to be secondary to severe orbital vasculitis.[107] The CT and MR imaging appearance of orbital lupoid disease may resemble that of the pseudotumors and lymphoreticular proliferative disorders.

Amyloidosis

Amyloidosis is caused by deposition of an amorphous hyaline material (amyloid) in various tissues such as muscle, skin, nerve, submucosa, adrenal gland, and the orbit. Involvement of the orbit and ocular adnexa may occur as part of primary hereditary systemic amyloidosis, as part of secondary amyloidosis, or as a localized isolated process.[17, 83, 116] The clinical features of orbital and adnexal amyloidosis include blepharoptosis, caused by infiltration of the levator muscle of the upper eyelid, and oculomotor palsies resulting from involvement of multiple extraocular muscles. When the lacrimal gland is involved, the disease resembles a lacrimal gland tumor. On CT, amyloid deposits (homogeneous eosinophilic protein) simulate pseudotumors, vascular malformation, and other mass lesions, and the deposits can occasionally calcify (Figs. 9-93 and 9-94A).[83] On MR imaging, the amyloid deposits have signal intensities similar to those of skeletal muscle on all imaging sequences (Fig. 9-94B). Localized amyloid infiltrations may affect the paranasal sinuses, and bone destruction has been reported.[83]

MISCELLANEOUS GRANULOMATOUS AND HISTIOCYTIC LESIONS

A number of pathologic entities are recognized that, except for fibrous histiocytoma, rarely involve the orbit. These include histiocytosis X (Langerhans' histiocytosis), Erdheim-Chester disease, juvenile xanthogranuloma, pseudorheumatoid nodules, necrobiotic xanthogranuloma, and fibrous histiocytoma.[3] All of these lesions bear a common feature based on local or systemic infiltration by histiocytes.[3] Fibrous histiocytoma is the most common tumor in this category.[5]

Langerhans' Cell Histiocytosis

A granulomatous disease that occurs in children more often than sarcoidosis or Wegener's granulomatosis is Langerhans' cell histiocytosis; the disease has a predilection for children between 1 and 4 years of age.[102] The term *histiocytosis X* was coined to describe a group of histiocytic conditions, with the letter X indicating their unknown nature.[116] It is now known that these histiocytic conditions result from the proliferation and infiltration of abnormal histiocytes within various tissues. These cells are morphologically and immunologically similar to Langerhans' cells, leading to the name *Langerhans' cell histiocytosis* (*Hand-Schuller-Christian disease*, *Letterer-Siwe disease*, and *eosinophilic granuloma*).[117] Hand-Schuller-Christian disease typically involves the triad of diabetes insipidus, proptosis, and destructive bone lesions, often involving the sphenoid bone. Letterer-Siwe disease is seen in children under 2 years of age and is characterized by an acute disseminated form of Langerhans'cell histiocytosis associated with hepatosplenomegaly, adenopathy, fever, thrombocytopenia, anemia, and cutaneous lesions. The diagnostic feature is the presence of abnormal aggregates of Langerhans' cells. These cells, unlike other histiocytes, are characterized by immunochemical positivity for S-100 protein and CD1a and by the ultrastructural presence of membranous cytoplasmic structures, 200 to 400 mm in width and shaped like tennis rackets, that are known as *Birbeck granules*.[102]

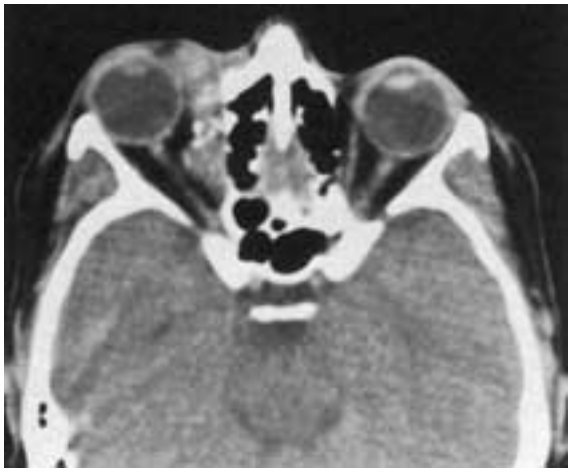

FIGURE 9-93 Amyloidosis of the right orbit with calcification. Axial CT section without infusion of contrast material reveals a mass in the extraconal space of the right orbit with a slight bulge into the intraconal space. Note the speckled calcifications within the amyloid deposit. The adjacent ethmoid sinus is normal. (From Weber AL, Mikulis DK. Inflammatory disorders of the paraorbital sinus and their complications. Radiol Clin North Am 1987;25:615–630.)

Note the retinal detachment of the right eye. **C**, Axial T1-weighted (600/25, TR/TE) MR image shows hypointensity of the amyloid deposit (**A**). Note the bilateral exudative retinal detachment. The amyloid deposit appeared markedly hypointense on T2-weighted MR images (not shown). (From Mafee MF et al. Lacrimal gland tumors and simulating lesions. Radiol Clin North Am 1999;37:219–239.)

It is generally agreed that histiocytic disorders can be divided into two general categories: (1) X histiocytic (Langerhans' cell), Langerhans' cell histiocytosis (LCH), and (2) non–X histiocytic (monocyte-macrophage type) proliferation, including juvenile xanthogranuloma (JXG).[118] All of these disorders are characterized by a localized proliferation of histiocytes, but they differ in their morphology, histochemical and immunohistochemical staining patterns, and electron microscopic features.[119] Furthermore, they differ in their clinical presentation and radiologic appearance. Recently, the Histiocyte Society has redefined the classification of the histiocytoses of childhood. Class I includes LCH; class II includes all the histiocytoses of the mononuclear phagocytes other than Langerhans' cells, such as juvenile JXG; and class III includes the malignant histiocytic disorders. Orbital histiocytic disorders are classified as LCH (histiocytosis X); sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman syndrome); JXG; Erdheim-Chester disease; necrobiotic xanthogranuloma (NXG); pseudorheumatoid nodule; and sarcoidosis.[118]

Historical Background

In 1953, Lichtenstein[116] introduced the term *histiocytosis X* for a group of diseases that include eosinophilic granuloma, Hand-Schuller-Christian disease, and Letterer-Siwe disease. He believed that the pathologic common denominator of all three conditions was a distinctive and specific inflammatory histiocytosis. The letter X was used to underscore the unknown nature of the disease. Using the Birbeck granule as a marker, Nezelof and Barbey[117] in 1985 reported that the lesions of histiocytosis X were the result of inappropriate proliferation and infiltration of various tissues with abnormal histiocytic cells that are morphologically and immunologically similar to Langerhans' cells of the Langerhans' cell system. Consequently, the name of the disease was changed to *Langerhans' cell histiocytosis*.[118–120] This is a disease of unknown etiology. Some investigators suggested that LCH may be a disorder of immune regulation; however, recently, some investigators have provided strong evidence that all forms of LCH are a clonal proliferative disease.[119, 121]

Clinical Features

The disease has a predilection for children 1 to 4 years old.[102, 119] Lesions in children are most commonly located in bone or bone marrow. Although LCH is a rare disease, in patients with the disease orbital involvement is not uncommon, and with few exceptions it is usually seen in the chronic form of the disease, especially eosinophilic granuloma. The overall incidence of orbital involvement in a series of 76 children with LCH was 23%.[118] The most common signs and symptoms of orbital LCH were unilateral or bilateral proptosis, edema, erythema of the eyelid, and periorbital pain. Other signs and symptoms were ptosis, optic nerve atrophy, and papilledema. The frontal bone was most commonly involved by LCH, and the lesions were usually seen in the superior or superolateral wall of the orbit

VIEW IMAGE

FIGURE 9-95 Langerhans' cell histiocytosis of the orbit. In addition to the mononuclear histiocytes, there are two multinucleated giant cells at the upper-right corner (*arrows*). ''Coffee bean'' nuclei are seen within the giant cells (hematoxylin-eosin, original magnification ×390). (From Hidayat AA et al. Langerhans' cell histiocytosis and juvenile granuloma of the orbit. Radiol Clin North Am 1998;36:1229–1240.)

in a rather anterior location. On rare occasions, the tumor may be noted in the orbital apex and superior orbital fissure without bone involvement. Classic cases of Hand-Schuller-Christian disease (the chronic disseminated form of LCH) with bilateral proptosis, diabetes insipidus, and bony defects of the skull are very rare.[118]

Ocular Manifestations

Intraocular involvement by LCH is rare and usually occurs as part of an acute disseminated form of the disease (i.e., Letterer-Siwe disease). In these cases, the uveal tract, particularly the choroid, is affected.[118]

Histopathologic Features

Grossly, the lesions are usually described as consisting of soft, friable, hemorrhagic, tan-yellow tissue. Histologically, the tumors are composed of sheets of large histiocytes with interspersed eosinophils, lymphocytes, and a few multinucleated giant cells (Fig. 9-95).

Immunohistochemistry

LCH cells are usually positive for the following immunologic markers: S-100 protein, peanut lectin, and CD1a (OKT-6).

Diagnostic Imaging

CT and MR imaging provide the most diagnostic assistance. Most lytic bony defects seen on standard plain films have been described as being irregular, serrated, and beveled, with or without a narrow zone of sclerosis. Orbital involvement may vary, but the most common orbital manifestation is a solitary lesion. In the typical case of orbital involvement, CT and MR imaging show an osteolytic lesion, commonly in the superior or superotemporal orbital region (Figs. 9-96 and 9-97). There is a fairly well-defined or diffuse soft-tissue mass encroaching on the lacrimal gland, the lateral rectus, or even the

globe. There may be extension of the soft tissue into the epidural space, as well as into the temporal fossa. There may be marked infiltration of temporalis muscles (Fig. 9-96). At times, multiple lesions may be present, resulting in multiple bony defects, particularly in the superolateral orbital roof region. Similar osseous lesions may be seen in the sphenoid, ethmoid, temporal, occipital, and parietal bones, as well as in the facial bones. Rarely, the lesion may be totally extraosseous. On postcontrast CT and MR imaging, lesions demonstrate moderate to marked enhancement (Fig. 9-97). The differential diagnosis of LCH from an imaging viewpoint includes rhabdomyosarcoma, juvenile fibrosarcoma, aggressive fibromatosis, lacrimal gland tumors, lymphoma, pseudotumor, leukemic infiltration, granulocytic sarcoma or chloroma, sinus histiocytosis, metastatic neuroblastoma, metastatic Wilms' tumor, and metastatic Ewing's sarcoma.

Juvenile Xanthogranuloma

Juvenile xanthogranuloma (JXG) (nevoxanthoendothelioma)[121] is a benign, usually self-healing disorder of infants, children, and occasionally adults. The disease is of unknown etiology and pathogenesis and represents a proliferation of non-Langerhans' (monocyte-macrophage) types of cells. The term *juvenile xanthogranuloma* was first introduced in 1936, but recognition of the entity did not occur until 1954.[118] Recently, the Histiocyte Society has redefined the classification of the histiocytoses of childhood and included JXG in class II.[118]

Copyright © 2003, Mosby, Inc. All rights reserved.

Clinical Features

Characteristically, the disease affects children, particularly infants, and is sometimes noted at birth. Adults are affected less frequently. The most common site is the skin, where spontaneous resolution is frequent.

Orbital involvement with JXG is rare, with only 15 patients having been described in the English literature, mostly as case reports, except for the series of 5 infantile cases in Zimmermans's[121] report and 5 adult cases reported by Jakobiec and coworkers.[122] Eight of these patients were infants, mostly less than 9 months old. In four of these infants, the orbital lesion was present since birth. In 7 of the 15 orbital cases, the patients were adults ranging from 22 to 60 years of age (average, 45 years).

Inside the eye, the most common sites of involvement are the iris and the ciliary body.[118] The retina, choroid, and optic nerve are rarely involved. In the eye, the presenting clinical signs, as described by Zimmerman,[121] are (1) asymptomatic localized or diffuse tumor of the iris; (2) congenital or acquired heterochromia of the iris; (3) unilateral glaucoma; (4) spontaneous hyphema; and (5) a red eye with signs of uveitis.[118, 121]

Central nervous system involvement by JXG has been reported with associated seizures, ataxia, subdural effusions, increased intracranial pressure, developmental delay, diabetes insipidus, and other neurologic deficits.[118] T1-weighted MR imaging of the brain showed solid, gadolinium-enhancing masses without evidence of cerebral edema or displacement.

Histopathologic Features

Histologically, the lesions are composed of foamy histiocytes, epithelioid monocytes, lymphocytes, plasma cells, eosinophils, Touton giant cells, and spindle cells (Fig. 9-98).[118] Touton giant cells are multinucleated cells with the nuclei grouped in a wreath-like arrangement around a small central island of nonfoamy cytoplasm (Fig. 9-98). In contrast, the peripheral cytoplasm is foamy. The numbers of the different histiocytic cells are variable and form four distinctive patterns with varying degrees of overlap: (1) xanthomatous, (2) xanthogranulomatous, (3) fibrohistiocytic, and (4) combined patterns. It should be noted that the number of foamy or lipidized cells can be few, and Touton giant cells can be rare or absent in some cases, thus making the histologic diagnosis extremely difficult, as noted in one of the reported cases of orbital JXG.[121] In that case, there were many eosinophils and the lesion closely resembled those of LCH. Histologically, the differential diagnosis of orbital JXG includes Erdheim-Chester disease, particularly in adult patients. In both conditions there are Touton giant cells and foamy histiocytes. The only subtle difference between these disorders is the increased amount of fibrosis with collagenization and cholesterol clefts in Erdheim-Chester disease. In such cases, the clinical and paraclinical data, such as metaphyseal radiopacities, pulmonary infiltration and fibrosis, cardiac decompensation, chronic lipogranulomatous pyelonephritis, retroperitoneal xanthogranuloma, and hyperlipidemia in Erdheim-Chester disease, are extremely important for establishing the correct diagnosis.[123, 124] Inflammatory pseudotumor does not show xanthoma or Touton giant cells histologically. The differential diagnosis also includes LCH. In both lesions eosinophils are present, but the histiocytes are different morphologically and immunohistochemically. Touton giant cells are present only in JXG. The foamy histiocytes and Touton giant cells are negative for S-100 protein; however, a few S-100-positive dendritic cells were reported in the peripheral areas of JXG lesions.

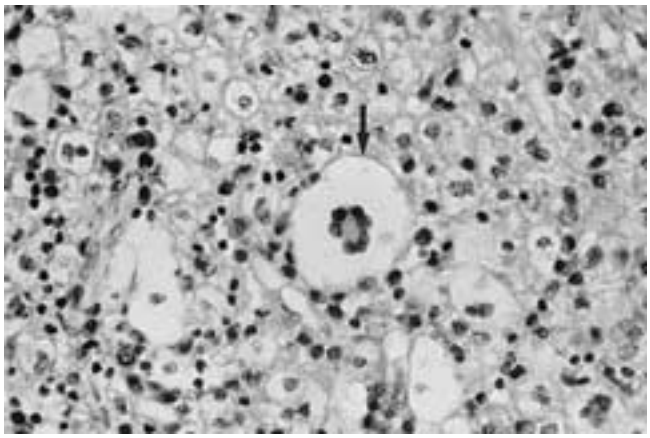

FIGURE 9-98 JXG of the orbit. Centrally, there is a characteristic multinucleated Touton giant cell (*arrow*), with the nuclei grouped in a wreath-like arrangement around a central small island of nonfoamy cytoplasm. The peripheral cytoplasm of the giant cell is pale and foamy. Other cells include xanthoma cells (lipidized histiocytes), with pale, foamy cytoplasm. A few lymphocytes are also present (hematoxylin-eosin, original magnification ×390). (From Hidayat AA et al. Langerhans' cell histiocytosis and juvenile granuloma of the orbit. Radiol Clin North Am 1998;36:1229–1240.)

VIEW IMAGE

Diagnostic Imaging

Radiologically, the most common ocular finding is involvement of the anterior portion of the eye (Fig. 9-99). It is important to know that the bony wall of the orbit may be involved.[119] These changes included simple erosions of the superior orbital rim in one patient, radiolucency in the malar eminence in another patient, and marked destruction of the roof and lateral wall of the orbit and of the greater wing of the sphenoid in a third patient.[119] Those cases with bone involvement may not be distinguished from LCH radiologically. There has also been a case in which the clinical and radiologic findings were typical of LCH (Hand-Schuller-Christian disease) in a 3-year-old girl who had bilateral proptosis and diabetes insipidus. However, the histopathology was more consistent with JXG (Fig. 9-100). Furthermore, the histiocytes were negative for the immunologic marker S-100 protein, and no Birbeck granules were found when electron microscopy was performed. The CT characteristics of orbital involvement of JXG in an adult are shown in Figure 9-101. It is important to realize that the inflammatory process, including the granulomatous disease involving the orbit, may simulate LCH. A case of orbital involvement by tuberculosis simulating LCH or JXG is shown in Figure 9-102.

Erdheim-Chester Disease

Erdheim-Chester disease is a peculiar form of systemic xanthogranulomatosis that occurs in adults.[123, 124] Most patients do not have orbital involvement. The first two cases

FIGURE 9-101 JXG of the orbit in an adult. **A**, Axial enhanced CT scans show proptosis and a diffuse infiltrative process involving the right orbit. There is abnormal soft-tissue thickening (*arrows*) of the left orbit as well. **B**, Enhanced axial CT scans show a marked infiltrative process involving the right orbit and, to a lesser extent, the left orbit. The differential CT diagnosis is bilateral pseudotumor, lymphoma, Wegener's granulomatosis, and necrobiotic xanthogranuloma. (From Hidayat AA et al. Langerhans' cell histiocytosis and juvenile granuloma of the orbit. Radiol Clin North Am 1998;36:1229–1240.)

were reported by Shields et al.[124] This disease is characterized by the infiltration of many organs including the lung, kidney, heart, bones, orbit, and retroperitoneal tissues. Orbital involvement tends to be bilateral. These patients present with progressive bilateral exophthalmos, which may lead to ophthalmoplegia, and visual loss secondary to compressive optic neuropathy.[92] CT and MR imaging may show extensive soft-tissue infiltration of the orbital fatty reticulum (Fig. 9-103).[107, 125] There may be no enhancement following the administration of Gd-DTPA contrast material.

Pseudorheumatoid Nodules

Pseudorheumatoid nodules usually occur as focal masses in the dermis of children. This disease may involve the

anterior orbit and periorbital region. The subcutaneous nodules consist of zonular granulomas surrounding necrobiotic collagen. These are thought to be more common in sites of previous trauma and are easily managed by simple excision[3] (Fig. 9-104).

Necrobiotic Xanthogranuloma

Necrobiotic xanthogranuloma is a histocytic disease characterized by multiple indurated xanthomatous subcutaneous nodules in patients with paraproteinemia and proliferative disorders such as multiple myeloma and leukemia.[3, 107, 126] Pathologically, a zonular granulomatous inflammatory infiltrate, with Touton giant cells and xanthoma cells, surrounds an area of necrobiosis. Ophthalmic manifestations are common and include xanthogranulomas involving the eyelid, orbit, conjunctiva, and orbital fatty reticulum.

TUMORS

Orbital Lymphoma

Orbital lymphomas are solid tumors of the immune system composed primarily of (monoclonal) B cells. The extranodal presentation of non-Hodgkin's lymphoma is common, with an incidence ranging from 21% to 64%. Roughly 10% of the cases of non-Hodgkin's lymphoma present in the head and neck region, and lymphoid tumors account for 10% to 15% of orbital masses.[89]

Lymphoid neoplasms of the orbit span a large continuum of various classifications ranging from the malignant lymphomas, to the benign pseudolymphomas or pseudotumors, to the reactive and atypical lymphoid hyperplasias.[91] There are no absolute imaging, clinical, or even laboratory tests that distinguish all types of benign orbital lymphoid lesions from orbital lymphomas or lesions that can simulate them.[91-93] A pleomorphic cellular infiltrate is correlated with more benign biologic activity, and the more uniform the cellular appearance, the greater the likelihood that a malignancy is present.[91] Of all patients with orbital lymphoma, 75% have or will have systemic lymphoma.[91] There is extensive overlap histologically from one type to another, and some forms of the benign process can transform over time into a more aggressive variety of lymphoma. True lymphoid tissue in the orbit is found in the subconjunctival and lacrimal glands, and these two areas account for most of the lymphoreticuloses developing in the orbit.[91, 94] The most common cytologic forms of malignant lymphoma involving the orbit are histiocytic and lymphocytic, with various degrees of differentiation. Both benign and malignant lymphoid tumors of the orbit occur predominantly in adults and are extremely rare in children.[6] The two main types of lymphoid tumor that ophthalmologists deal with are reactive lymphoid hyperplasia, a localized benign disease of unknown cause, and malignant lymphoma, which may either arise in and be limited to the orbit, may arise in the sinonasal cavities and extend into the orbit, or may be one focus of a systemic lymphoma.[6] Clinically, both malignant lymphoma and reactive lymphoid hyperplasia can produce a painless progressive proptosis accompanied by extraocular motility disturbance, visual disturbance, and lacrimal gland enlargement.[6] Any orbital tissue or combination of tissues may be involved in either disease process.[6] All patients with benign and malignant lymphoid lesions of the orbit should be subjected to systemic evaluation to rule out a systemic lymphoproliferative disorder. Intracranial involvement is extremely uncommon in patients with lymphoma at the time of presentation, but such involvement occasionally occurs in some patients with persistent disease.[102] A few patients with Hodgkin's disease, Burkitt's lymphoma, and other non-Hodgkin's lymphomas have presented with the Tolosa-Hunt syndrome.[102] Outside the original lymphoid tissue of Waldeyer's ring, there is a mixed population of lymphocytes

FIGURE 9-106 Lymphomatoid granulomatosis. Contrast-enhanced axial CT scan shows diffuse infiltration of the intraconal space of the right orbit (*arrows*) with putty-like molding of the process around the posterior globe. CT features of this T-cell lymphoma precursor are virtually identical to those of true lymphoma, pseudotumor, lupoid infiltration, and metastatic carcinoma associated with marked proliferation of dense connective tissue surrounding malignant cells, such as in scirrhous carcinoma (breast, stomach).

that reside in the subepithelial area of the nasal cavity. A smaller population of lymphocytes is scattered among the submucosal glands and within the deep vascular stroma; extranodal B-cell non-Hodgkin's lymphoma derives from these cells.[115] In most cases, multiple sinuses are affected. Involvement of one or more paranasal sinuses is more typical of B-cell lymphoma, whereas involvement of the nasal cavity is more typical of T-cell lymphoma.[102] Less commonly, the lymphomas (generally those of a T-cell phenotype) invade adjacent sites such as the orbit, and patients present with diplopia, blurred vision, and paralysis of the cranial nerves.[102]

Diagnostic Imaging

Ultrasound, CT, and MR imaging can be used to evaluate orbital lymphomas. CT and MR imaging have made it possible to make a strong presumptive diagnosis of orbital lymphoma, especially when the CT and MR imaging features are examined in conjunction with the clinical signs and symptoms.[131] The CT and MR imaging findings are usually nonspecific, and based solely on imaging, it may be impossible to differentiate the lymphomas from orbital pseudotumors (Figs. 9-105 to 9-107), lacrimal gland tumors (Fig. 9-107), optic nerve tumors, Graves' orbitopathy, primary orbital tumors, or orbital cellulitis.[127–131] Orbital lymphomas are homogeneous masses of relatively high density and sharp margins, which are more often seen in the anterior portion of the orbit, the retrobulbar area (Fig. 9-108), or in the superior orbital compartment. CT and MR

imaging may reveal a putty-like molding of the tumor to preexisting structures without eroding the bone or enlarging the orbit.[127, 128] Mild to moderate enhancement is usually present (Figs. 9-106 to 9-108).[127, 131]

All orbital lymphoid tumors tend to mold themselves around the orbital structures without producing bony erosion (Figs. 9-108 and 9-109). Specifically, a bulky lesion in the region of the lacrimal fossa that does not produce bony erosion is most likely to be either inflammatory or lymphoid in character (Figs. 9-109 and 9-110).[17, 131] However, the aggressive malignant lymphomas can produce frank destruction of bone.[131] Lacrimal gland lymphoma displaces the globe medially and forward and appears as a moderately enhancing mass that diffusely involves the gland (Figs. 9-110 and 9-111).[127] Deformity of the globe's shape is rare.

MR imaging has proven to be as sensitive as CT for the diagnosis of orbital lymphoma and pseudotumors. Both pseudotumors and lymphoma may have intermediate or low signal intensity on T1-weighted and proton density images and appear isointense to fat on T2-weighted images (Figs. 9-111 and 9-112).[127]

Lymphoplasmacytic Tumor (Plasma Cell Tumor)

Tumors composed purely of plasma cells (plasmacytomas) and those composed of B lymphocytes and plasma cells (lymphoplasmacytoid tumors) are closely related to the various lymphomas.[3, 107] The plasma cell is actually a B lymphocyte that has become modified to produce large quantities of immunoglobulin.[107] These so-called plasmacytoid lymphomas may secrete IgM paraprotein in sufficient quantities to cause a monoclonal peak in the serum; this is classically seen in Waldenstrom's macroglobulinemia.[3] One of the important tumors composed of plasma cells is multiple myeloma (Fig. 9-113). There are also solitary forms of extramedullary plasmacytomas, which are not associated with systemic multiple myeloma.[107] These plasma cell tumors, particularly as they affect the orbit and ocular structures, display the same spectrum of clinical involvement seen in the lymphoproliferative disorders (Fig. 9-113).[3] Both isolated plasmacytoma and Waldenstrom's macroglobulinemia can produce a mass that can be visualized by both CT and MR imaging. The mass may be lobulated, densely enhancing, and well defined, and can be present with or without bone erosion (Fig. 9-114).[3] In systemic myelomatosis, a permeative or moth-eaten pattern of bone destruction or gross destruction may be present.[71]

ORBITAL LEUKEMIA

Leukemia is one of the most common childhood cancers. It is estimated that of the approximately 7100 cases of childhood cancer in the United States each year, 35% are leukemia.[107, 126] Leukemic disorders in children fall mainly into the lymphoid and myeloid groups. About 75% of the cases are acute lymphoblastic leukemia, 20% are acute myelogenous leukemia (AML), and 5% are chronic myelogenous leukemia.[107] Chronic lymphocytic leukemia is a disease of adulthood and almost never affects children.[107] The eye and adnexa are not infrequently involved (Fig. 9-115). Orbital involvement with leukemia is the result of direct infiltration of the orbital bone or soft tissue by leukemic cells (Fig. 9-116). In patients with AML, such infiltration most often occurs in the form of a granulocytic sarcoma (Fig. 9-117). A granulocytic sarcoma is commonly called a *chloroma* because the myeloperoxidase within the tumor imparts a green hue to it, as seen on gross examination.[107] This may be the first manifestation of AML in many patients. The lesion typically involves the orbital subperiosteal space, usually affecting the lateral wall of the orbit, with extensions to the temporal fossa. Medial orbital wall disease also occurs with involvement of ethmoid air cells, the cribriform plate, and the anterior cranial fossa. There may be dural or leptomeningeal infiltration, demonstrating enhancement on enhanced CT and MR imaging. The imaging differential diagnosis includes rhabdomyosarcoma, LCH, subperiosteal abscess, subperiosteal hematoma, lymphoma, pseudotumor, and metastasis (neuroblastoma, Ewing's sarcoma, and Wilms' tumor).

ORBITAL VASCULAR CONDITIONS

Vascular lesions of the orbit represent an important group of orbital pathologies, particularly in infants and children. They also are the most controversial group of lesions because of confusion regarding their nature, and a debate continues as to the classification of the various vascular malformations that may involve the orbit.[132] In general, orbital vascular lesions include capillary hemangioma, cavernous hemangioma (cavernoma, a venous malformation), varices (venous malformation), lymphangioma, lymph-

angiovenous (venolymphatic) malformation, arteriovenous malformation, ''sclerosing hemangioma,'' hemangiopericytoma, and hemangioendotheliomas (angiosarcomas).

Capillary Hemangioma (Benign Hemangioendothelioma)

Capillary hemangiomas are tumors that occur primarily in infants during the first year of life. The tumor often increases in size for 6 to 10 months and then gradually involutes.[8, 17, 132, 133] It occurs most commonly in the superior nasal quadrant. Microscopically, the tumor is composed of endothelial and capillary vessel proliferations with benign endothelial cells surrounding small, capillary-sized vascular spaces.[8, 17, 132] Capillary hemangiomas in and

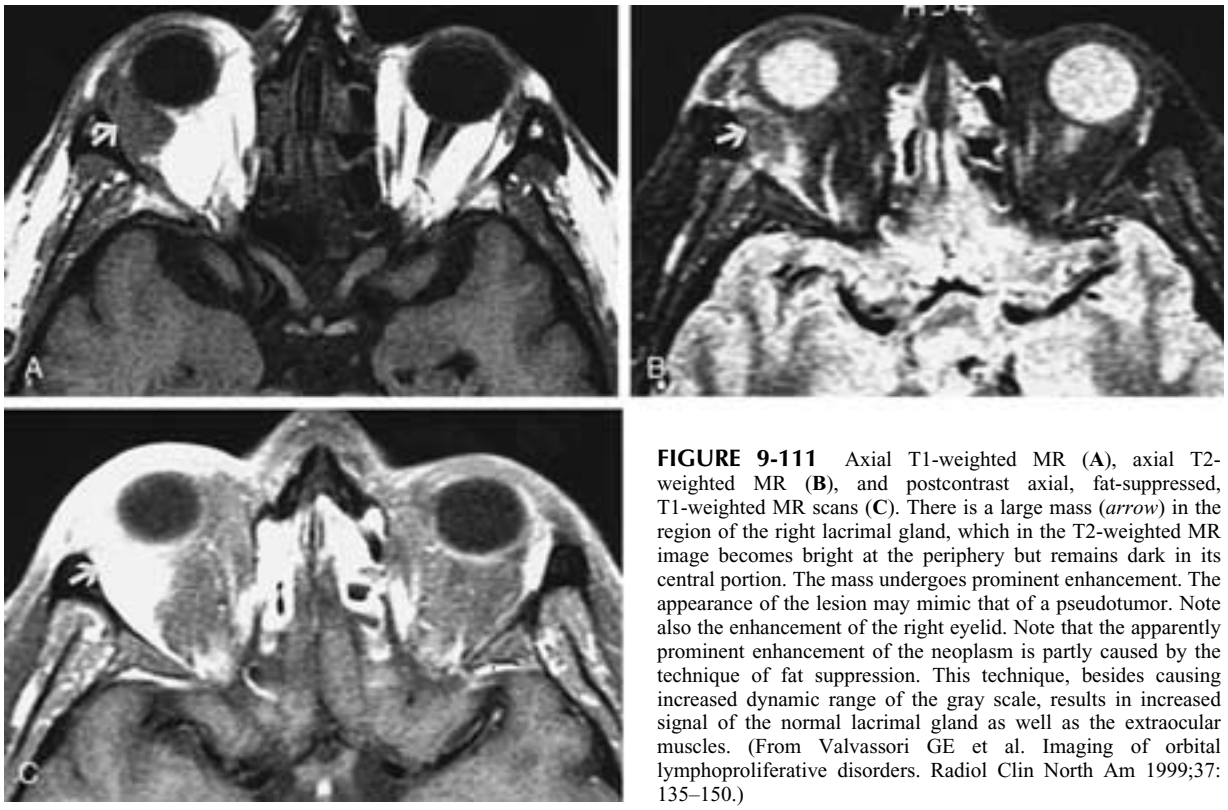

FIGURE 9-111 Axial T1-weighted MR (**A**), axial T2-weighted MR (**B**), and postcontrast axial, fat-suppressed, T1-weighted MR scans (**C**). There is a large mass (*arrow*) in the region of the right lacrimal gland, which in the T2-weighted MR image becomes bright at the periphery but remains dark in its central portion. The mass undergoes prominent enhancement. The appearance of the lesion may mimic that of a pseudotumor. Note also the enhancement of the right eyelid. Note that the apparently prominent enhancement of the neoplasm is partly caused by the technique of fat suppression. This technique, besides causing increased dynamic range of the gray scale, results in increased signal of the normal lacrimal gland as well as the extraocular muscles. (From Valvassori GE et al. Imaging of orbital lymphoproliferative disorders. Radiol Clin North Am 1999;37: 135–150.)

VIEW IMAGE

around the orbit may have an arterial supply from either the external carotid or internal carotid arteries, and these tumors are capable of bleeding profusely.[8, 132, 133] These hemangiomas may extend intracranially through the superior orbital fissure (Fig. 9-118), optic canal, and orbital roof. On CT these lesions are seen as fairly well-marginated (Fig. 9-118) to poorly marginated, irregular, enhancing lesions. Most are extraconal, although some of them may be seen in the intraconal space (Fig. 9-119). On dynamic CT, capillary hemangiomas characteristically show intense homogeneous enhancement (Fig. 9-120). On MR imaging, capillary hemangiomas appear as hypointense or slightly hyperintense to brain on T1-weighted images and hyperintense to brain on proton density and T2-weighted images. They show intense enhancement following the intravenous injection of Gd-DTPA contrast material. On MR angiography (MRA) the vascularity of these lesions may not be appreciated. Therefore, at present, one should not rely only on MRA for the diagnosis of these capillary hemangiomas.

Cavernous Hemangioma

Cavernous hemangioma of the orbit, the most common orbital vascular tumor in adults, has distinctive clinical and histopathologic features.[7, 17, 132] It tends to occur in the second to fourth decades of life. These tumors show a slowly progressive enlargement distinct from that of capillary hemangiomas, which gradually diminish in size. In contrast to capillary hemangiomas, a prominent arterial supply is usually absent.[8] Cavernous hemangiomas possess a distinct fibrous pseudocapsule and therefore, on CT and MR imaging, appear as well-defined masses (Figs. 9-121 and 9-122). This observation, in addition to the fact that they are usually independent of the general circulation, enables excision of the entire lesion without fragmentation.[8] These hemangiomas may be located anywhere in the orbit but frequently (83%) occur within the retrobulbar muscle cone (Figs. 9-121 to 9-123). On CT, cavernous hemangiomas appear as well-defined, smoothly marginated, homogeneous, rounded, ovoid, or lobulated soft-tissue masses of increased density and variable contrast enhancement (Fig. 9-121). Unless they are ruptured or surgically violated, cavernous hemangiomas always respect the contour of the globe (Fig. 9-124). The MR imaging characteristics of hemangiomas are shown in Figure 9-122. Histologically, cavernous hemangiomas are composed of large, dilated vascular channels (sinusoid-like spaces) lined by thin, attenuated endothelial cells.[8, 17, 132] At times, intraconal cavernous hemangiomas may be difficult to differentiate

from other intraconal lesions such as meningiomas, hemangiopericytomas, and schwannomas.[8, 17, 132] Uncommonly, an intramuscular hemangioma may occur (Fig. 9-125). Orbital bone modeling is not uncommon in cavernous hemangiomas, and at times, calcification may be seen in these lesions. *Sclerosing hemangioma* is another less well defined term used to describe hemangiomas that show prominent sclerosis. These lesions often show foci of calcification (Fig. 9-126).

Lymphangioma

Although the origin of lymphangioma may remain controversial, the lesion is an unencapsulated mass consisting mostly of bloodless vascular and lymph channels.[73] Connective tissue between the channels may contain foci of lymphoid cells that proliferate in viral infections, resulting in the clinical finding of worsening proptosis when the child has an upper respiratory tract infection.[73] Orbital lymphangiomas occur in children and young adults. In contrast to the rapid, self-limited growth of infantile capillary hemangiomas, lymphangiomas gradually and progressively enlarge during the first two decades of life.[8, 132] Cavernous lymphangiomas are composed of delicate endothelium-lined, lymph-filled sinuses (filled with clear fluid or chocolate-colored, unclotted fluid) that invade the surrounding connective tissue stroma.[8, 73, 132] The interstitial tissue often shows lymphoid follicles and lymphocytic infiltration.[8] Spontaneous (or after minor trauma) hemorrhage within the lesion is common, resulting in a chocolate cyst.[8, 17] Lymphangiomas may have distinct borders but are typically diffuse and not well encapsulated (Figs. 9-127 and 9-128), with portions of the lesion infiltrating normal tissues of the lid and orbit.[8, 17] They are usually multilobular (Fig. 9-128), and because complete surgical excision is seldom

accomplished, recurrence is common.[8, 132] They are more common in the extraconal space.[8]

On CT these lymphangiomas appear as poorly circumscribed, often heterogeneous masses of increased density in the extraconal or intraconal space (Fig. 9-127). Bony remodeling may be present, calcification is rare, and minimal to marked contrast enhancement may be present (Fig. 9-127). On MR imaging, lymphangiomas are relatively hypointense or hyperintense to brain on T1-weighted images and usually very hyperintense on T2-weighted images (Figs. 9-128 and 9-129). Fluid-fluid levels related to hemorrhages of various ages are characteristic of lymphangioma. Their MR imaging characteristics should help differentiate them from pseudotumors and hemangiomas (Fig. 9-129).[8]

Orbital Varix

Primary orbital varices are congenital venous malformations characterized by proliferation of venous elements and massive dilation of one or more orbital veins, presumably associated with congenital weakness in the venous wall.[8, 17, 73, 134] A varix may include a single smooth-contoured, dilated vein, a single vessel with segmental dilatation, or a tangled mass of venous channels.[73] Varices within the orbit may appear to have both cystic (chocolate) and solid components.[73] Orbital varices are the most common cause of spontaneous orbital hemorrhage.[135] Clinically, proptosis or globe displacement increases during a Valsalva maneuver, reflecting the varix's connection to the venous system.[73] The CT appearance of orbital varix may be normal in axial sections (Fig. 9-130A), but because of increased venous pressure, it is quite abnormal in coronal

sections, particularly those obtained in the prone position (Figs. 9-130B and 9-131). Because the varix may be completely collapsed or barely visible when the patient is lying quietly supine, any time an orbital varix is suspected, it is recommended that additional CT sections be obtained during a Valsalva maneuver. In a patient suspected of having an orbital varix, MR imaging also should be performed with the patient in the prone position. Some varices may have such a small communication with the systemic venous system that they are undistensible. Because they have stagnant blood flow, they manifest themselves by thrombosis and hemorrhage.[132] Venous anomalies of the orbit including varices may be associated with contiguous or noncontiguous intracranial venous anomalies.[132] Orbital varices may also be secondary to intracranial vascular malformations, particularly arteriovenous shunts.[172] MR imaging of orbital varices usually shows a varix to be hyperintense on T1-weighted, proton density, and T2-weighted images (Fig. 9-132). At times, an orbital varix may have the same MR imaging characteristics as a cavernous

hemangioma or other orbital masses, being hypointense on T1-weighted, hyperintense on T2-weighted, and enhanced on postcontrast T1-weighted MR images. An orbital varix may also be seen as several round or tubular structures with associated calcifications (phleboliths) (Fig. 9-133).[8]

Carotid Cavernous Fistulas and Arteriovenous Malformations

Carotid cavernous fistulas produce proptosis, chemosis, venous engorgement, pulsating exophthalmos, and an auscultable bruit. Ischemic ocular necrosis resulting from a carotid-cavernous fistula has also been reported.[17, 136] A carotid cavernous fistula may result from trauma or surgery, or it may occur spontaneously. Spontaneous carotid-cavernous fistulas have been reported in patients with osteogenesis imperfecta, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum. In these cases, the fistula probably

VIEW IMAGE

resulted from weakness of the vessel walls related to the connective tissue disease.[136] CT and MR imaging demonstrate proptosis, with engorgement of the superior ophthalmic vein and frequent enlargement of the ipsilateral extraocular muscles (Fig. 9-134). There may be CT or MR imaging evidence of venous thrombosis in the lumen of the superior ophthalmic vein or cavernous sinus. Arteriovenous shunts within the orbit itself are rare.[132] At times, anomalous intracranial venous malformations, as well as dural vascular malformations and fistulas, may mimic the imaging appearance of carotid cavernous fistulas (Fig. 9-135).[136] Angiographic demonstration of the exact location of the carotid-cavernous fistula is essential to plan definitive therapy.

Hemangiopericytoma

Hemangiopericytomas are rare, slow-growing vascular neoplasms that arise from unique cells called *pericytes of Zimmermann*, which normally envelop capillaries and postcapillary venules of practically all types of tissues.[8, 137–139] Histologically, these tumors are composed of scattered, capillary-like spaces surrounded by proliferating pericytes.[8] Hemangiopericytomas may be divided into lobules by fibrovascular septa.[8, 137] About 50% of the cases are malignant, and distant metastases, although uncommon, occur via the vascular and lymphatic routes.[8, 140] Most such metastases go to the lungs.[8, 137, 139] If not excised completely, these lesions tend to recur, and wide surgical excision is the treatment of choice.

On CT, the margins of an orbital hemangiopericytoma, in contrast to those of a cavernous hemangioma, may be slightly less distinct owing to its tendency to invade the adjacent tissues (Fig. 9-136).[8, 17] Erosion of the underlying bone may be present (Fig. 9-137), and marked contrast enhancement favors a diagnosis of hemangiopericytoma. MR imaging may not differentiate these tumors from cavernous hemangiomas, neurogenic tumors, meningiomas, and other lesions (Fig. 9-138), but angiography may

differentiate the tumors from cavernous hemangiomas, meningiomas, and schwannomas.[8] Hemangiopericytomas usually have an early florid blush (Fig. 9-136C), and cavernous hemangiomas show a late minor pooling of contrast or often appear as avascular masses.[8, 134, 141] Meningiomas may show multiple tumor vessels and a late blush, and schwannomas may show no tumor blush.[8, 17, 140, 141] Hemangiopericytomas may be difficult to differentiate from other rare vasculogenic tumors such as angioleiomyomas, malignant hemangioendotheliomas (angiosarcomas), and fibrous histiocytomas.[8] Follow-up CT or MR imaging is extremely important to diagnose tumor recurrences (Fig. 9-137B).

rilemmomas or schwannomas.[142] Of these, 2% of the lesions are plexiform neurofibromatosis, 1% are isolated neurofibromas, and 1% are schwannomas.[142] Malignant peripheral nerve tumors (malignant schwannoma, neurofibrosarcoma) are extremely rare in the orbit.[142]

Neurofibroma

Neurofibromas may occur in one of four patterns: (1) plexiform, (2) diffuse, (3) localized or circumscribed, and (4) postamputation neuromas.[142] When most of the fascicles in a segment of peripheral nerve are involved, cylindrical enlargement of the entire nerve segment is observed. This clinical and gross pathologic configuration is referred to as *plexiform neurofibroma*.[7, 17, 142] Plexiform neurofibromas present in infancy or childhood and most commonly involve the eyelids. The tumor consists of cords and nodules giving rise to a ''bag of worms'' on palpation, and a plexiform neurofibroma involving the eyelid is considered to be virtually pathognomonic for neurofibromatosis (Von Recklinghausen's disease).[142] Diffuse neurofibromas have an appearance similar to that of plexiform neurofibromatosis, with infiltration of the orbital fat and EOMs, but these lesions are less likely to be associated with Von Recklinghausen's disease.[142] Circumscribed or localized neurofibromas often present as slow-growing tumors that exert a mass effect, with displacement of the globe. The tumor may occur along any sensory nerve but is more common in the superior quadrants. When arising from the lacrimal nerve, it may have the clinical appearance of a lacrimal gland tumor.

Copyright © 2003, Mosby, Inc. All rights reserved.

Histologically, plexiform neurofibromas are unencapsulated and have an organoid appearance, with proliferating units surrounded by perineurium enclosing axons, Schwann cells, and endoneurial fibroblasts. There is a marked increase in vascularity, which leads to profuse bleeding at the time of surgery.

This increased vascularity is responsible for marked contrast enhancement on CT and MR imaging. The CT and MR imaging appearance of plexiform neurofibromatosis in infants and children may be identical to that of a capillary hemangioma. Solitary neurofibromas often demonstrate a pseudocapsule, but a true perineurium is not seen. They are composed of wavy bundles of peripheral nerve sheath cells with comma-shaped nuclei and hyaluronic acid and collagen in the stroma.[142] The CT and MR imaging characteristics of neurofibroma are shown in Figures 9-138 to 9-140.

Schwannomas are benign, slow-growing nerve sheath tumors that account for 1% of all orbital tumors.[7,106, 107, 142] They may arise anywhere within the orbit, although they are most common in the intraconal space.[7] Their malignant counterpart, the malignant schwannoma (malignant neurolemma, neurogenic sarcoma, and fibrosarcoma of the nerve sheath), is exceedingly rare in the orbit.[7, 142] In general, neurofibromas and schwannomas are two benign tumors originating from Schwann cells that occur in the orbit as isolated lesions or in association with neurofibromatosis. The optic nerve has no Schwann cells; therefore, orbital schwannomas must arise from peripheral nerve fibers of

nerves III, IV, V, VI, VII, and the autonomic nerves. Schwannomas and neurofibromas are differentiated primarily on the basis of histopathology. Schwannomas are well encapsulated by the perineurium of the nerve of origin and, in contrast to neurofibromas, display clear evidence of Schwann cell origin.[142] Histologically, they are surrounded by a thin fibrous capsule that is formed by compression of perineural tissue. The tumor is composed of compactly arranged spindle-shaped cells that interlace in cords and whorls frequently oriented with their long axis parallel to one another. This cellular pattern is referred to as *Antoni type A*.[7, 107, 142] Commonly, the Antoni type B part of the tumor has a less cellular pattern characterized by haphazardly distributed cells in a collagenous matrix.[7, 17, 107, 142] On CT and MR imaging, orbital schwannomas appear as sharply marginated, oval or fusiform, intraconal or extraconal masses that demonstrate moderate to marked enhancement (Figs. 9-141 and 9-142). The optic nerve is always displaced and may be engulfed by the tumor (Fig. 9-141). The differential diagnosis includes cavernous hemangioma, meningioma, fibrous histiocytoma, neurofibroma, fibrocystoma, hemangiopericytoma, and metastasis.

TUMORAL AND NONTUMORAL ENLARGEMENT OF THE OPTIC NERVE SHEATH

Optic nerve sheath meningiomas and gliomas are the most common tumors involving the optic nerves, resulting in localized or diffuse enlargement of the optic nerve sheath complex (see Chapter 11). Primary or secondary involvement of the optic nerve in cases of lymphoma (Fig. 9-85), sarcoid (Fig. 9-86), leukemia, tuberculosis, toxoplasmosis, and syphilis has been reported.[16, 17, 27, 83] Optic nerve sarcoid manifesting as an enhanced tumor on CT and MR imaging scans can be easily mistaken for optic nerve sheath meningioma (Figs. 9-86, 9-88). Other rare causes of enlargement of the optic nerve include intradural cavernoma of the optic nerve and hemangioblastoma of the optic nerve, characteristically seen in patients with von Hippel-Lindau disease (Fig. 9-143).

OPTIC NEURITIS

This condition is an acute inflammatory process involving the optic nerve that may present as optic nerve enlargement.[16] Multiple sclerosis is the most common cause of optic neuritis and visual loss is typically unilateral, although it may be bilateral.[143] Optic neuropathies following chicken pox, rubella, rubeola, mumps, herpes zoster, mononucleosis, and viral encephalitis are referred to as *parainfections*, as opposed to those caused by direct tissue infiltration by microorganisms.[143] Visual loss is typically bilateral, occurring 10 to 14 days after the primary illness.

VIEW IMAGE

This delay suggests a cascade of autoimmune mechanisms. Optic neuritis in patients with systemic lupus erythematosus or other autoimmune states is referred to as *autoimmune optic neuritis*.[143] Infective causes of optic neuritis include syphilis (neuroretinitis, papillitis, and perineuritis); toxoplasmosis; toxocariasis (papillitis); and, uncommonly, borreliosis (Lyme disease) and other granulomatous diseases.[143] Radiation optic neuropathy is another cause of optic neuritis. Optic neuritis in children differs from that in adults, including a greater incidence of disc swelling and a tendency toward bilateral simultaneous involvement.[143] Optic neuritis is often an early manifestation of multiple

sclerosis, and on CT there may be some enlargement of the optic nerve, usually with some degree of contrast enhancement (Fig. 9-144). On MR imaging the optic nerve may appear thickened and hyperintense on T2-weighted images (Fig. 9-145), and the MR visualization of multiple sclerosis plaques may be accentuated by inversion recovery (STIR) technique.[16, 83] Postcontrast fat-suppressed, T1-weighted MR images may be the best technique to demonstrate optic neuritis, and localized or diffuse areas of enhancement are typically seen within the nerve (Figs. 9-146 and 9-147). In general in patients with optic neuritis, contrast enhancement on CT and MR imaging is often subtle or present in a short segment of the optic nerve, particularly in the intracanalicular portion of the nerve (Fig. 9-146).

PNEUMOSINUS DILATANS

Pneumosinus dilatans is a rare condition in which dilated paranasal sinuses lined by normal mucosa are present. In these hyperpneumatized paranasal sinuses, excessive pneumatization can lead to thinning and gross dehiscence of the bony wall. When there is actual bone dehiscence, the lesion is usually referred to as a *pneumocele* (see Chapter 5). The frontal sinus is most commonly affected, but the sphenoid sinus is the most important for visual loss because of its intimate relation with the optic canal.[144] Sphenoidal or sphenoethmoidal pneumosinus dilatans may be associated with visual symptoms.[144] Pneumosinus dilatans has been associated with meningioma and fibroosseous lesions, and pneumosinus dilatans without an associate pathologic process rarely causes visual loss (Fig. 9-148). The mechanism leading to optic neuropathy is uncertain, although with

direct communication between the sinus and the optic canal present, one could postulate a direct compressive effect by mucosa or air leading to ischemic nerve damage.[144] It has been suggested that sudden elevation of the intrasinus pressure, as with sneezing or with altitude change (in airplanes), may cause direct damage to an exposed optic nerve.[144]

FIBROUS TISSUE TUMORS OF THE ORBIT

Fibrous tumors of the orbit are a group of lesions that present a confusing clinical, histologic, and imaging spectrum of disease. These include fibroma, fibrous histiocytoma, fibrocystoma, aggressive fibromatosis, nodular fasciitis, and fibrosarcoma. Fibrohistiocytic tumors are more common than fibroblastic (fibroma, fibromatosis) tumors.[145]

Fibrous Histiocytoma

Fibrous histiocytoma is a mesenchymal tumor that involves the fascia, muscle, and soft tissues of the body.[3, 145–148] It is considered by some authors to be the most common mesenchymal tumor of the orbit.[146] The neoplasm is made up of fibroblasts, myofibroblasts, undifferentiated mesenchymal cells, and fibrous-appearing histiocytic cells that tend to form a characteristic cartwheel or storiform pattern.[3, 145–148] Fibrous histiocytoma probably arises from a fibroblast precursor, and it bears no relationship to the systemic reticuloendothelioses or malignant histiocytoses. The tumor may be either benign or malignant.[146, 147] Malignant fibrous histiocytomas produce bone erosion. Benign lesions cause a mass effect with compressive bone atrophy (remodeling).[7] Fibrous histiocytomas are seen on CT and MR imaging as well-circumscribed masses that may be intraconal or extraconal and demonstrate

Radiol Clin North Am 1987;25:529–559.)

moderate to marked contrast enhancement (Figs. 9-149 and 9-150).[145] Some of the tumors may be bilobed. Some of the densely cellular fibrous histiocytomas may appear moderately to markedly hypointense on T2-weighted images, and these lesions may not be differentiated on imaging from some of the neurofibromas and other fibrous lesions (Fig. 9-151). The differential diagnosis should include cavernous hemangioma, hemangiopericytoma, schwannoma, meningioma, neurofibroma, fibrocystoma, vasculogenic leiomyoma, lymphoma, and metastasis. Malignant fibrous histiocytomas may be seen following irradiation of the orbit for retinoblastoma.[17]

Fibroma and Fibrosarcoma

Fibroma is the least common fibrous tumor of the orbit and is found mostly in young adults.[145] It is usually encapsulated and grows slowly over several years. It arises from the fascia of the EOMs or Tenon's capsule in the orbit. Fibrosarcoma is also rare in the orbit. Congenital, infantile, juvenile, and adult forms of fibrosarcoma are recognized.[145] Aggressive fibromatosis is a benign but locally invasive fibroblastic lesion lying clinically and pathologically in the spectrum between fibrosis and low-grade fibrosarcoma. Infantile deep (desmoid type), infantile myofibromatosis (congenital generalized fibromatosis), and adult (deep or musculoaponeurotic) forms are recognized (Fig. 9-152).

The lesion may be (1) solitary in about 73%; (2) multicentric, involving subcutaneous tissues, skeletal muscle, and the ends of long bones; or (3) generalized, with cutaneous, musculoskeletal, and visceral involvement.[145] Orbital involvement may rarely be bilateral.[145] Fibromatosis tends to be locally infiltrative and grows rapidly, which may cause it to be considered as a low-grade fibrosarcoma. Histologically, it is composed of well-differentiated, uniform fibroblasts, appearing similar to smooth muscle, but electron microscopy reveals that the lesion contains fibroblasts and myofibroblasts. Treatment is wide surgical excision. Fibromatosis recurs locally in 25% to 65% of cases and can be fatal. CT and MR imaging may show a lesion with either benign-appearing or invasive characteristics (Fig. 9-152).

Nodular Fasciitis

Nodular fasciitis is a common fibrous tumor found elsewhere in the limbs and trunk of adults, but head and neck involvement is seen more commonly in infants and children.[145] Orbital involvement may develop in the lid, conjunctiva, Tenon's capsule, or the deep orbit.[145] Microscopically, plump fibroblasts have a stellate appearance. Normal mitosis is present. The pathologic differential diagnosis should include fibromatosis, fibrosarcoma, leiomyoma, neurofibroma, schwannoma, myxofibrosarcoma, and myxoid liposarcoma.[145] Nodular fasciitis is best treated with complete excision and has a recurrence rate of 1% to 2%.[145] CT and MR imaging findings are nonspecific and similar to those of aggressive fibromatosis (Fig. 9-153).

RHABDOMYOSARCOMA OF THE ORBIT

Although rhabdomyosarcoma (RMS) is a rare tumor, it is still the most common primary orbital malignancy in children and the most common soft-tissue malignancy of childhood. Soft-tissue sarcomas account for 6% of all childhood cancers, and RMS accounts for approximately 50% of all pediatric soft-tissue sarcomas and 15% of all pediatric solid tumors.[149–153] Approximately 250 new pediatric patients are diagnosed with RMS each year in the United States. The head and neck area accounts for 35% of all RMS, the genitourinary system for 23%, and the extremities for 17%. The remainder are found in the trunk, retroperitoneum, chest, perineum, and gastrointestinal tract.[149–153] RMS occurs primarily in patients from ages 2 to 5; however, the tumor may occur at any age from birth to adulthood. In most cases, the average age at diagnosis is 7 to 8 years. RMS can be further divided into bimodal age peaks, depending on the histology. The embryonal and alveolar subtypes present in children, and the pleomorphic type presents more commonly in adults. The tumor may even be present at birth.[149] Orbital RMS is invariably unilateral, and although the tumor may involve any part of the orbit and adnexa, it tends to involve the superior portion of the orbit. The most characteristic presenting features of orbital RMS are a fairly rapid onset and progression, with proptosis and displacement of the globe.

RMS originates from embryonic tissue, either from immature prospective muscle fibers or pluripotential embryonic mesenchymal tissue, with a potential for aberrant differentiation into muscle fibers. Cytogenic analysis has found that many of these patients have a translocation between chromosomes 2 and 13 and abnormalities of chromosome 11.[149–153] This tumor does not originate from preformed extraocular striated muscles. The differential diagnosis also includes leukemic and metastatic deposits (neuroblastoma), lymphoma, LCH, aggressive fibromatosis, plexiform neurofibromatosis, ruptured dermoid cyst, sub-

Copyright © 2003, Mosby, Inc. All rights reserved.

periosteal hematoma after trauma, and a chocolate cyst related to hemorrhage in a lymphangioma. RMSs are pleomorphic tumors, and the cells may be anaplastic. On the basis of their histopathologic characteristics, RMSs are classified into one of three histologic types: (1) embryonal, (2) differentiated, and (3) alveolar. Differentiated RMS is the least frequent type and is rarely misdiagnosed because cells with eosinophilic cytoplasmic fibrils that are usually cross-striated are used to identify the tumor. Embryonal RMS, the most common histologic subtype, is believed to arise from the primitive muscle cell, because it is found in 7- to 10-week-old fetuses. The histologic differentiation between embryonal and alveolar RMS may be difficult. It has been estimated that up to 50% of proved cases of RMS are misdiagnosed on initial biopsy.[149]

RMS of the sinonasal tract and orbit often presents as a

FIGURE 9-150 Malignant fibrous histiocytoma. Axial (**A**) and coronal (**B**) contrast-enhanced CT. The contrast-enhanced CT studies on this 58-year-old man demonstrate a well-defined, moderately enhancing mass at the left lateral globe margin, which indents the globe without visibly invading the dense sclera. A small amount of gas is present in the mass after needle biopsy. **C**, Coronal T1-weighted image (TR/TE = 600/12) reveals that the mass is intermediate in signal intensity. **D**, Axial, fat-saturation, T1-weighted image (600/12) shows moderate gadolinium enhancement. **E**, Axial, conventional, STIR (TR/TE/T1 = 2000/43/170) image shows that the mass is hyperintense to temporalis muscle, slightly hypointense to the vitreous, and separated from the globe contents by the hypointense band of sclera. At surgery, it arose from the ciliary body near the tendinous insertion of the lateral rectus muscle. (From Dalley RW. Fibrous histocytoma and fibrous tissue tumors of the orbit. FIGURE 9-153 Nodular fasciitis. A 36-year-old man presented with an apparent inflammatory left orbital mass, which was unresponsive to 3 weeks of antibiotics. Axial (**A**) and coronal (**B**) contrast-enhanced CT. Soft-tissue windows show an ill-defined, enhancing, extraconal or subperiosteal soft-tissue mass in the left superior-lateral orbit, with a low-attenuation central area (*arrowheads*). Note the subtle enhancement along the anterior cranial fossa (*arrow*). **C**, Coronal CT bone windows demonstrate focal erosion in the frontal bone adjacent to this low-attenuation region (*arrowhead*). **D**, Coronal T1-weighted image (600/15) reveals an intermediate intensity extending lateral to the orbital rim in addition to eroding the frontal bone. **E**, Coronal, fat-saturation, postgadolinium, T1-weighted image (650/15). After gadolinium, most of the mass enhances, with a central, nonenhancing focus adjacent to the bone erosion. Note the intracranial dural reaction (*arrow*). **F**, Coronal, fast-STIR (2000/12/160) image. The mass is isointense to gray matter, with a focal area of hyperintensity corresponding to the cystic-appearing region on the postgadolinium image. The preoperative diagnosis was ruptured dermoid cyst or an aggressive lacrimal region abscess with osteomyelitis. (From Dalley RW. Fibrous histocytoma and fibrous tissue tumors of the orbit. Radiol Clin North Am 1999;37:185–194.)

relatively innocuous problem (e.g., recurrent sinusitis, proptosis, or a small nasoorbital mass). Secondary sinonasal tumors may arise from adjacent orbital spread of orbital or pharyngeal RMS. RMSs are aggressive bone-destroying and bone-pushing lesions. Although RMS of the orbit is most often seen in children and in adults under 20 years of age, at times it affects older patients.

RMS, nonrhabdomyosarcomatous soft-tissue sarcoma, and Ewing's sarcoma occur frequently in the head and neck of children. The nonrhabdomyosarcomatous sarcomas in-

clude fibrosarcoma, angiosarcoma, malignant fibrous histiocytoma, malignant schwannoma and neurofibroma, leiomyosarcoma, hemangiopericytoma, synovial sarcoma, and other less common sarcomas. Rao et al.[154] reported 110 cases of nonrhabdomyosarcomatous soft-tissue sarcomas. Head and neck sites accounted for only 15% of these tumors. The head and neck sites can be divided into three broad groups: (1) cranial parameningeal, (2) orbital, and (3) nonorbital-nonparameningeal.[149] Parameningeal RMS refers to those tumors arising in the nasopharynx, paranasal sinuses, nose, middle ear, temporal fossa, and pterygopalatine fossa. Nonorbital-nonparameningeal head lesions include superficial and deeply placed tumors, including tumors of the scalp and face, as well as deep tumors arising in the buccal mucosa, parapharyngeal space, larynx, salivary gland, and neck.[149]

Proptosis is an uncommon finding in children, but the vast majority of space-occupying lesions in the orbit causing proptosis in children are benign. These include inflammatory lesions (infection, abscess, and idiopathic orbital inflammation); developmental cysts (teratoma, dermoid, epidermoid); subperiosteal hematoma; benign and malignant mesenchymal tumors (osteogenic, chondrogenic, histiocytomatous, fibromatous [aggressive fibromatosis], lipomatous, myxomatous, rhabdomyomatous); tumors of vascular origin (hemangioma and lymphangioma); metastases; and neurogenic tumors (neurofibroma, plexiform neurofibromatosis, optic nerve glioma). Although malignant lesions are rare, clinically they can mimic more common benign processes, creating difficulty in diagnosis. Other orbital malignancies include lymphoma (including Burkitt's lymphoma), leukemia, extension of retinoblastoma, metastatic neuroblastoma, and secondary involvement by Ewing's sarcoma. Radiologic imaging is an essential aid to the clinician in differentiating the diagnostic possibilities.

Orbital RMS generally presents painlessly with rapidly progressive unilateral exophthalmos or, less commonly, as a superficial swelling with a palpable mass and proptosis. Patients may even present with a confusing or misleading history, such as recent trauma. Orbital RMS usually affects young children or adolescents up to age 16 years, with an average age of 7 years, but has been reported in older children and adults. Most tumors are retrobulbar, resulting in proptosis, but they can arise extraconally, especially superiorly or supranasally. They have also been reported to arise intraocularly from the ciliary body.[149] Tumors arising in the paranasal sinuses, nasal cavity, pterygopalatine fossa, nasopharynx, and parapharyngeal space may secondarily invade the orbit, and RMS arising elsewhere can metastasize to the orbit.[149]

Of the head and neck sites, orbital RMS has a better outlook, presumably because of the paucity of lymphatics and tumor confinement by the bony orbit. Parameningeal involvement is associated with the poorest outcome, presumably because of abundant lymphatics and the lack of confinement to prevent extension into the surrounding tissues.

Diagnostic Imaging

CT and MR imaging play an important role in the preoperative evaluation and staging of these tumors. Imaging should include CT and MR imaging of the primary and metastatic sites (i.e., lung, liver, brain, and so forth). CT and MR imaging are also important in evaluating recurrent and residual disease, and a baseline CT or MR imaging study is essential following completion of treatment. Without a baseline CT or MR scan, the follow-up studies may not be specific for tumor recurrence. Because of the dramatic improvement in survival of patients treated promptly with appropriate chemotherapy and radiation therapy, these tumors must be diagnosed as soon as possible.

On CT images, the RMSs are isodense in relation to normal muscles and appear as homogeneous, well-defined soft-tissue masses without bone destruction (Fig. 9-154). Larger tumors appear as less well defined soft-tissue masses with bone destruction or invasion of surrounding structures (Fig. 9-155). Tumors that have focal hemorrhage appear heterogeneous on CT scans. All tumors demonstrate moderate to marked contrast enhancement.[149]

On T1-weighted MR images, the RMSs are isointense or slightly hypointense compared with brain. On T2-weighted MR images, they appear to have increased signal intensity compared with brain (Fig. 9-156). Tumors that have chronic or subacute areas of hemorrhage demonstrate focal areas of increased signal on T1-weighted and T2-weighted images.[152] RMS demonstrates enhancement on contrast-enhanced CT and MR images (Fig. 9-157).[149] With the fat-suppression technique, T1-weighted images demonstrate marked expansion of the gray scale, with apparently increased signal intensity of the normal EOMs and lacrimal glands. Therefore, these normal structures should not be mistaken for tumor. The tumors appear more hyperintense on postcontrast fat-suppressed, T1-weighted images than on postcontrast non-fat-suppressed T1-weighted images.

When the diagnosis is suspected, cross-sectional imaging primarily with CT or MR imaging is performed to confirm the presence of an infiltrative mass and evaluate the extent of involvement of adjacent structures, including the brain. Although both may be equivalent in detecting an abnormal mass and determining its origin, MR imaging better delineates the full extent of involvement due to its superior soft-tissue contrast (Fig. 9-158).

Concomitant reactive sinus disease can be differentiated on MR imaging by differences in signal intensity on SE and postcontrast images. Superimposed fungal infection, during or following radiation therapy and chemotherapy, may pose

a problem for the radiologist in distinguishing residual tumor from invasive fungal infection. The resultant bone destruction or remodeling about the orbit and cranium is common with advanced disease and is best evaluated with CT. It is still possible, however, to detect bony invasion by the distortion of the bone marrow signal on MR imaging, especially after the administration of contrast.

Many common and less common orbital and head and neck neoplasms, however, such as hemangiomas, lymphangiomas, lymphoma, leukemic infiltration, plexiform neurofibromatosis, aggressive fibromatosis, pseudorheumatoid nodule, and pseudotumor, can appear similar to RMS, with similar CT and MR imaging characteristics. Thus, the findings are nonspecific in many cases, necessitating a tissue diagnosis. Subperiosteal hematoma in children may simulate RMS. MR imaging in these cases may be extremely valuable to make the correct diagnosis. Orbital pseudotumors in children can simulate orbital RMS (Fig. 9-159), as can aggressive fibromatosis RMS (Fig. 9-152). Capillary hem-

angiomas and other vasculogenic lesions (Fig. 9-160), including vascular malformations, may also simulate RMS, and dynamic CT may be very helpful in the diagnosis of capillary hemangiomas. At times, RMS may present with a clinical picture and imaging features of an orbital subperiosteal abscess.[155] In adults, lymphoma and primary and secondary orbital tumors should be included in the differential diagnosis (Fig. 9-161).

Imaging also allows planning of biopsy and surgery. Although superficial disease is easily accessible to the clinician, deeply seated masses present technical difficulties. Radiologic guidance (i.e., CT) may be used to direct aspiration biopsy safely, with minimal risk and morbidity. Further workup for staging should be performed including chest radiographs, a blood count, liver function tests, skeletal survey, bone marrow biopsy, etc. Surgery is performed to remove the maximum amount of tumor tissue that is safely feasible while minimizing the resulting deformity. Thus, staging depends on resection of the primary mass, the amount of residual tumor, and the presence of distant metastases, which usually involve the lung, bone marrow, lymph nodes, and brain. Due to the absence of lymphatics about the orbit, regional lymph nodes tend not to be involved, at least until advanced spread has occurred.

Once the diagnosis is confirmed by pathologic analysis, prompt treatment is initiated to maximize the patient's chances of survival. Currently, treatment includes biopsy or excision and radiation therapy with adjuvant chemotherapy. Smaller focal lesions may be entirely removed safely, whereas larger masses or metastatic lesions usually have

residual disease after extirpation. Regardless, radiation therapy helps control the local residual tumor, which may be microscopic and/or due to incomplete excision. The addition of combination chemotherapy has been shown to improve survival. Complete resection of a local tumor or minimal residual tumor after removal of regional disease allows 90% or greater survival after 5 years. With significant residual tumor, the prognosis drops to 35%. The major side effects of therapy are vision problems due to cataracts, retinopathy, and corneal scarring from keratoconjunctivitis. Other late side effects include bony orbital deformity and enophthalmos, secondary malignancy (leukemia), and leukoencephalopathy. Improvements in treatment regimens and decreases in radiation doses have decreased secondary complications.

After treatment is instituted, cross-sectional imaging can be used to objectively monitor tumor regression or residual and recurrent disease (Figs. 9-162 and 9-163). In fact, an increased risk of relapse is associated with posttreatment residual tissue, and residual tissue can be shown with CT or MR imaging prior to any clinical relapse. A relapse, in turn, denotes a poor prognosis; thus, early detection is essential. Clinical abnormalities and symptoms usually occur with recurrence, initiating further imaging to confirm the suspicion. Recurrent disease usually occurs locally in the surgical bed or regionally in the adjacent central nervous system. It is difficult to differentiate fibrosis and scarring from active tumor with CT and MR imaging, particularly if no baseline study is available. On the other hand, healing of bone destruction may signify a response to therapy and can be easily evaluated by CT. Furthermore, MR imaging of the brain may be helpful to monitor for, or follow up on, associated parenchymal leukoencephalopathic changes resulting from chemotherapy and radiation therapy, which may be subtle in the early stages. CT is less sensitive in this latter situation.

MESENCHYMAL CHONDROSARCOMA OF THE ORBIT

Extraskeletal malignant cartilaginous tumors are subdivided into two major categories: mesenchymal and myxoid chondrosarcoma. Mesenchymal chondrosarcomas commonly occur within the bones. Extraskeletal locations include the head and neck, the cranial and spinal dura mater, and, less frequently, the leg, especially the thigh.[156] Orbital mesenchymal chondrosarcoma (OMC) remains an extremely rare entity occurring more frequently in young women.[156–159] The most common presenting symptom of OMC is proptosis, with orbital pain, diplopia, and headache. Histologically, OMC is relatively distinct, containing islands of chondroid tissue. The cartilaginous areas have the appearance of mature cartilage. Most of them contain amorphic calcification and foci of ossification of the cartilaginous matrix.[156, 158] Other areas of undifferentiated mesenchymal tissue are seen, with a predominance of spindle-shaped cells. Mitoses are not frequent. In addition, areas of dilated vascular channels in the stroma can be seen that histologically resemble hemangiopericytoma.[156–159]

CT imaging characteristics include a relatively well-defined soft-tissue mass with areas of mottled, coarse calcification (Fig. 9-164A), and moderate, delayed contrast enhancement is noted. MR imaging characteristics include a signal intensity lower than or equal to that of brain on T1-weighted images and isointense to brain on T2-weighted images, with moderate enhancement after gadolinium contrast administration (Fig. 9-164B-F). The calcified component of the tumor shows low signal on both T1-weighted and T2-weighted MR images (Fig. 9-164B,F). On enhanced T1-weighted MR images, however, mild enhancement is seen even within the calcified components (Fig. 9-164D,E).[156]

The differential diagnosis for an intraorbital calcified mass includes meningioma, sclerosing hemangioma, hemangiopericytoma, vascular malformation, varix, and orbital amyloidosis.[8, 156] Calcification in cavernous hemangioma, fibrous histiocytoma, fibrocystoma, schwannoma, neurofibroma, and optic glioma is extremely rare. Hemangiopericytomas may occasionally demonstrate dystrophic calcification, which is usually seen after recurrence of the lesion.[156] Fibrous histiocytomas are the most common adult mesenchymal tumors of the orbit, presenting as well-circumscribed intraconal or extraconal masses with moderate to marked enhancement. The more cellular fibrous histiocytomas may have moderately or markedly low signal intensity on T2-weighted MR images.[156] This MR appearance may mimic that of OMC; however, unlike OMC, fibrous histiocytomas do not show calcification on CT scans. Orbital amyloidosis demonstrates a soft-tissue mass with coarse, streaky, amorphous calcification diffusely scattered throughout the lesion (Figs. 9-93 and 9-94). In addition, certain areas that appear to be calcific density actually represent amyloid (Figs. 9-93 and 9-94).[156]

LACRIMAL GLAND AND FOSSA LESIONS

The lacrimal gland is about the size and shape of an almond and is located in the superolateral extraconal orbital fat in the lacrimal fossa, adjacent to the tendons of the superior and lateral rectus muscles. The more anterior palpebral lobe is separated from the deeper orbital lobe by the lateral horn of the levator muscle aponeurosis.[24, 120] The lacrimal gland is a modified salivary gland, and it can be involved by a wide spectrum of orbital pathology. Meticulous clinical and preoperative imaging of these patients is imperative so that an inappropriate incisional biopsy is avoided. This situation is especially true when a benign mixed tumor of the lacrimal gland is suspected. This tumor requires en bloc excision through a lateral orbitotomy to ensure complete extirpation and prevent late recurrences.[24] If an incisional biopsy of a benign mixed tumor is performed, there is an increased likelihood of operative tumor spillage and thus late recurrences.[24, 160, 161] The excellent prognosis of benign mixed tumor, provided that it is completely removed at the first surgery, is now widely accepted.

Lesions of the lacrimal gland and fossa present special problems in diagnosis and management. Because of the importance of preoperative diagnosis, all clinical ancillary findings should be integrated into the assessment of individual cases. In general, epithelial tumors represent about 50% of the masses involving the lacrimal gland. The remaining 50% of lacrimal gland masses are either lymphoid or inflammatory in nature.[24, 160] Metastasis to the parenchyma of the lacrimal gland is rare.[24] Dermoid cysts are not true lacrimal gland tumors; rather, they arise from epithelial rests located in the orbit, particularly in the superolateral quadrant. Epithelial cysts, on the other hand, are intrinsic lesions that result from dilation of the lacrimal ducts.[24, 160]

Inflammatory diseases of the lacrimal gland can be divided into two categories, acute and chronic.[24] Acute dacryoadenitis (bacterial or viral) is more commonly seen in children and in younger people.[24, 156, 162, 163] It may be related to trauma and clinically is associated with local

tenderness, erythema, lid swelling, conjunctival chemosis, discharge or suppuration, enlarged preauricular and cervical nodes, and systemic findings.[24, 156] Acute dacryoadenitis is usually unilateral and tends to respond very rapidly to therapy.[24, 156] It may be part of the spectrum of idiopathic inflammatory orbital pseudotumor, and this diagnosis is made often on the basis of the clinical presentation, CT findings, and the prompt and favorable response to the administration of systemic corticosteroids.[24, 156, 163, 164]

Chronic dacryoadenitis may follow acute infection or may be caused by sarcoidosis (Fig. 9-165), thyroid ophthalmopathy, Mikulicz's syndrome, Sjogren's syn-

drome, ''sclerosing pseudotumors'' (Fig. 9-166), and Wegener's granulomatosis. In sarcoid there is usually bilateral disease, with either symmetric or asymmetric lacrimal gland enlargement (Fig. 9-165). Mikulicz's syndrome is a nonspecific swelling of the lacrimal gland and salivary glands associated with conditions such as leukemia, lymphoma, pseudotumor, tuberculosis, syphilis, and sarcoidosis. In Sjogren's syndrome, there is enlargement of and lymphocytic infiltration of the lacrimal glands. Half of these patients have a connective tissue disease such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, or polymyositis. Inflammatory pseudotumor in the region of the lacrimal gland accounts for about 15% of all orbital pseudotumors (Fig. 9-107).[156, 164] Although this disease is rare in the very young, the age variation is quite wide. The most common symptoms include proptosis, swollen lids, pain, and diplopia, and in the majority of patients the duration of symptoms is less than 6 months. Wegener's granulomatosis is characterized by necrotizing granulomas of the respiratory tract, renal failure, and a disseminated focal necrotizing angiitis of small arteries and veins.[24, 82, 165] Ocular involvement in Wegener's granulomatosis is common, affecting 40% of patients with generalized disease.[24, 82] Involvement of the lacrimal gland is not uncommon (Fig. 9-91). Histologic examination of involved lacrimal glands shows infiltration with histiocytes, plasma cells, lymphocytes, polymorphs, and eosinophils, with giant cell formation.[24, 164] Massive enlargement of lacrimal glands may be present and has been demonstrated on CT.[24, 164] Lymphomatous lesions of the lacrimal gland include a broad spectrum ranging from reactive lymphoid hyperplasia to malignant lymphomas of various types (Fig. 9-167). It can be very difficult to differentiate pathologically between benign lymphocytic infiltration and lymphoma other than to note in a general way that lymphomas tend to occur in older patients. Shield et al., in a review of 645 space-occupying orbital lesions that underwent biopsy, found 71 cases of lymphocytic and plasmacytic lesions.[165, 166] Of these, 12 were located in the lacrimal gland.

Benign mixed lacrimal gland tumors tend to occur in patients in the third to sixth decades of life. The tumors present with slowly progressive, painless upper lid swelling, proptosis, or both, without inflammatory symptoms or signs (Fig. 9-168). Malignant tumors also occur but may not be diagnosed as such on imaging unless there is adjacent bone destruction.

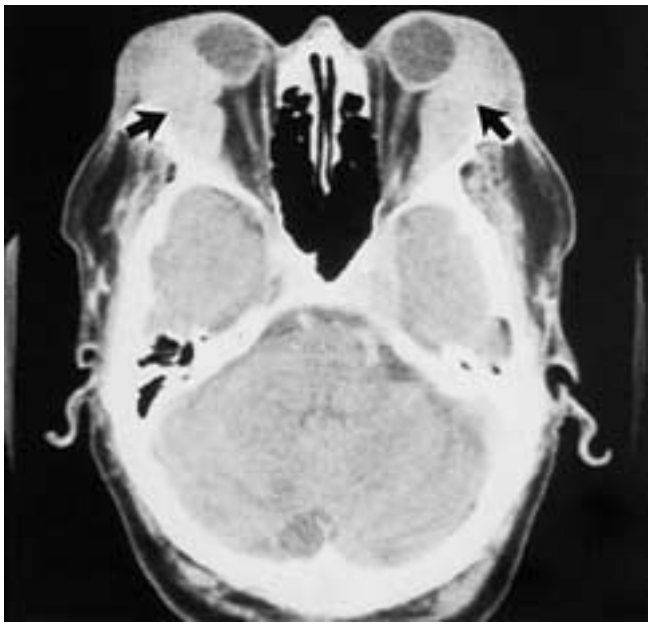

FIGURE 9-166 Lacrimal gland pseudotumor. An 80-year-old patient with swelling of both eyes. Axial postcontrast CT scan shows bilateral lobular enlargement of the lacrimal glands (*arrows*).

Diagnostic Imaging

Inflammatory lesions of the lacrimal gland cause diffuse enlargement of the gland. Contrast enhancement may be marked, and there may be associated acute lateral rectus muscle myositis. There may be associated scleritis with fluid in Tenon's space and a ring of uveoscleral enhancement. In chronic dacryoadenitis, the gland also shows diffuse oblong enlargement (Figs. 9-165 and 9-166). The glands may be massively enlarged in cases of sarcoidosis (Figs. 9-165), or in other conditions such as Mikulicz's syndrome, pseudotu-

VIEW IMAGE

mor (Fig. 9-166), and Wegener's granulomatosis.[24, 82, 164] However, in these patients, scleral enhancement is not an associated feature, as it is in patients with acute inflammation.

Benign and malignant lymphoid tumors situated in the lacrimal gland also display diffuse enlargement with oblong contouring of the gland (Fig. 9-107).[24, 164] However, these lesions are usually bulky (Fig. 9-110), frequently have anterior and posterior extension, and mold and drape themselves on the globe. In general, inflammatory processes and lymphomas tend to involve all aspects of the lacrimal gland, often including its palpebral lobe (Figs. 9-107 and 9-110). By comparison, neoplastic lesions rarely originate in the palpebral lobe of the gland, and therefore there is often only posterior extension of the mass rather than anterior growth beyond the orbital rim (Figs. 9-168 to 9-170).

Because the lacrimal gland is histologically similar to a salivary gland, the diseases that affect these glands are similar and epithelial tumors represent 50% of the masses involving the lacrimal gland.[24, 160, 164] Half of these tumors are pleomorphic (benign mixed) adenomas, and the other half are malignant lesions. Of the malignant tumors,

adenocystic carcinoma is the most common, followed by pleomorphic (malignant mixed tumor, carcinoma ex-pleomorphic adenoma), mucoepidermoid carcinoma, adenocarcinoma (Fig. 9-167), squamous cell carcinoma, and undifferentiated (anaplastic) carcinoma. A significant number of these tumors arise within pleomorphic adenomas as carcinoma ex-pleomorphic adenomas.[24, 158] Benign mixed tumors may undergo spontaneous malignant degeneration and are increasingly likely to undergo such malignant degeneration the longer they exist.[158, 161, 165] In such a malignant mixed tumor, the malignant cell clone develops from the preexisting benign mixed tumor, and the malignancy is often a poorly differentiated adenocarcinoma or an adenoid cystic carcinoma.[24, 164] In general, patients with these carcinomas have a poor prognosis.[24, 157]

In 1979 Stewart et al. described a scheme for the clinical diagnosis and management of lacrimal fossa pathology that classified these lesions using distinguishing clinical features and plain film radiographs.[157] Jakobiec et al.[161] performed a study evaluating the clinical and CT findings in 39 patients with four different kinds of lacrimal gland swelling. Sixteen of these patients had a parenchymal benign or malignant tumor. This study added a new diagnostic criterion, the ''contour analysis'' of the shape of the mass, as a factor to be combined with the clinical history. Stewart et al. reviewed 31 cases of benign and malignant lacrimal gland masses.[157] Fourteen patients had benign mixed lacrimal gland tumors, and 13 had pressure changes characterized by enlargement of the lacrimal fossa without destruction of bone. Sclerosis of bone was present in one patient. Malignant neoplasms accounted for 17 of the 31 tumors. Twelve patients had pressure changes, two had no bone changes, and three showed destructive changes. Three patients with pressure changes and malignant tumors had calcification in the lacrimal gland fossa. Two patients had sclerosis of bone adjacent to the lacrimal fossa.

In the series of Jakobiec et al.,[161] benign tumors had smooth, encapsulated outlines, whereas the malignant tumors displayed microserrations indicative of infiltration. In their series, inflammatory conditions demonstrated diffuse, compressed, and molded enlargement of the lacrimal gland in an oblong fashion, and there were no associated bone defects. This study concluded that well-encapsulated, rounded masses of long duration were likely to be benign mixed tumors. The epithelial neoplasms probably began unicentrally within the lacrimal gland and

FIGURE 9-171 Lacrimal gland cyst. Axial CT scan shows a lacrimal gland cyst (*arrow*). This epithelial cyst developed in the orbital component of the lacrimal gland. (From Mafee MF et al. Lacrimal gland tumors and simulating lesions. Radiol Clin North Am 1999;37:219–239.)

grew in a centrifugal fashion in all directions, sometimes indenting the globe, distorting its muscle cone, and creating fossa or bone destruction in the orbital walls.[161] By contrast, inflammatory and lymphoid lesions of the lacrimal gland were seen as diffuse expansions of the lacrimal gland, and the lesions molded themselves to preexisting orbital structures without eroding bone or enlarging the orbit.[161, 164] The study found that the stroma of the epithelial tumors was often hyalinized or even cartilaginous and that this tissue was less likely than inflammatory or lymphoid tissue to mold, in a putty-like fashion, to the isthmus between the globe and the orbital bone.[161, 164]

Bony changes in the lacrimal gland fossa may be produced by either benign or malignant epithelial tumors.[24] However, bone changes also can be produced by a lacrimal gland cyst (Fig. 9-171) and by other orbital lesions such as schwannoma, neurofibroma, fibrous histiocytoma, and lesions originating within the subperiosteal space or bone such as a benign orbital cyst, hematic cyst (Fig. 9-172), cholesterol granuloma, LCH (in particular eosinophilic granuloma), dermoid cyst, epidermoid cyst, or metastatic carcinoma.[161] Lymphoid and inflammatory processes rarely produce bone changes.[24]

MISCELLANEOUS LACRIMAL GLAND LESIONS

Amyloid Tumor of the Lacrimal Gland

Infiltration of the lacrimal gland with amyloid is a very uncommon disorder.[164] Amyloidosis of the lacrimal gland and orbit usually is associated with the primary localized variant of the disorder, although it can be seen as a secondary form of the disease due to degeneration and amyloid depositions.[164] Isolated lacrimal gland involvement is rare and may mimic inflammatory, infiltrative, and even neoplastic diseases of the lacrimal gland. The CT and MR imaging findings of lacrimal gland amyloidosis consist of an enlarged lacrimal gland with or without calcification. Amorphous calcification of the lacrimal gland should raise the possibility of lacrimal amyloidosis (Fig. 9-94A), and calcifications may also be multiple, resembling phleboliths.[164]

Kimura's Disease

Kimura's disease is a chronic self-limited inflammatory condition of unknown etiology and a rare cause of a tumor-like mass in the head and neck.[164] Kimura et al.[167] reported this entity in 1948. Kimura's disease was long regarded as synonymous with angiolymphoid hyperplasia with eosinophilia; however, it is now clear that they are separate entities despite having some similar histologic features (also see Chapter 36).[164] Patients typically present with painless tumor-like nodules in the head and neck region, often associated with regional lymphadenopathy. Peripheral blood eosinophilia and an elevated serum level of IgE are almost always present.[164] Histologically, Kimura's disease is characterized by a mixed lymphoeosinophilic infiltration, reactive lymphoid follicles, ill-defined fibrosis, and capillary proliferation. Major salivary glands as well as the lacrimal gland may be involved in Kimura's disease.[164] The CT appearance of Kimura's disease is shown in Figure 9-173. The differential diagnosis of Kimura's disease of the lacrimal gland includes dacryoadenitis, sarcoidosis, pseudotumor, lymphoma, and lacrimal gland and fossa tumors.[164]

SECONDARY ORBITAL TUMORS

Malignant tumors of the sinonasal cavities may invade the orbit directly. Tumors of the skin of the face, such as basal cell and squamous cell carcinomas and malignant melanoma, can invade the orbit. The inferior orbital fissure is a pathway for tumors arising from or extending into the pterygopalatine or infratemporal fossae. Adenoid cystic tumors of the oral cavity and sinonasal cavities, as well as squamous cell carcinoma and lymphoma of the sinonasal-oral cavities, can extend along the perineural-perivascular pathways into the pterygopalatine fossa and then into the

VIEW IMAGE

orbit. Intracranial lesions such as meningioma may extend through the posterolateral wall of the orbit, the optic canal, the sphenoid fissures, the ethmoidal foramina, or less resistant bony walls such as the lamina papyracea and orbital roof. Metastases to the orbit are most commonly the result of breast carcinoma in women (Fig. 9-172) and carcinoma of the lung, kidney, or prostate in men (Fig. 9-174). In children, metastases are from primary neuroblastoma, Ewing's sarcoma, and Wilms' tumor. Metastases can simulate primary tumors, myositis, or diffuse orbital pseudotumor (notably breast carcinoma), and a multiplicity of lesions can be helpful in suggesting the diagnosis of metastatic disease. Metastatic lesions may occur in any of the orbital compartments.[168] At times, a metastatic deposit may be single and well defined, simulating benign orbital tumors. This appearance has been seen in patients with known or unknown primary malignant melanoma and carcinoid tumor. In patients who have undergone enucleation for malignant uveal melanoma, retinoblastoma, and ocular medulloepithelioma, any tumor mass within the surgical bed should be considered a metastatic recurrence.

ADDITIONAL PATHOLOGIES OF THE EXTRAOCULAR MUSCLES

Ocular Motility Disorders

Ocular muscle disturbances (strabismus) are relatively common, occurring at a rate of approximately 2% to 4%.[15] While the onset is usually in infancy or early childhood, acquired forms may occur at any age. If the object being viewed does not fall on the macula of both eyes, strabismus exists and the position of the nonaligned eye determines the description of the type of deviation (esotropia = inward deviation, exotropia = outward deviation; vertical imbalance described as hyper- or hypotropia).[15]

Strabismus is frequently divided into two types based on the diagnostic and therapeutic implications. In comitant types of strabismus, movement is not limited in any field of gaze, nor is there evidence of a paretic muscle. The etiology is thought to be abnormalities in higher brain centers. By contrast, noncomitant strabismus is characterized by limited ocular movement due to lesions involving the brainstem, cerebral centers, or cranial nerves; to muscle damage; or to any process causing restricted movement of the EOMs and resulting in asymmetric movements. These two possible etiologies of noncomitant strabismus, neurologic and restrictive, can often be distinguished by a forced duction test that shows no impediment to passive movement of the eye with forceps when there is neurologic damage compared to limitation on attempted movement of the globe in restrictive disease of the EOM. For example, in a diabetic lateral rectus palsy, the eye may be passively moved freely, whereas in thyroid myopathy, when an attempt is made to rotate the eye with a forceps, the examiner experiences restriction to movement in one or more fields of gaze.[15]

The use of CT and MR imaging has improved our understanding of many congenital and acquired conditions causing strabismus. This results in more appropriate therapeutic intervention and gives insight into the pathophysiology of these conditions.[15]

When evaluating the relative size of EOMs, particularly the horizontal muscles (the medial rectus and lateral rectus), it is important to know where the patient is fixing his or her gaze at the time of scanning. The Sherrington law of reciprocal innervation states that when the agonist muscle contracts, an inhibitory impulse is sent to the antagonist muscle, which then relaxes and lengthens. These actions are essential for normal full range of ocular movement. Therefore, when the patient is looking at the right field of gaze, there is an increase in the size of the contracting right lateral and left medial rectus muscles and a decrease in the relaxed left lateral and right medial rectus muscles. If this is not appreciated when analyzing the CT scan, an inappropriate diagnosis of an enlarged muscle can be made (Fig. 9-12). In most clinical situations, it is preferable to have the patient fix his or her gaze in the straight-ahead position, and it is

useful to place some fixation target at a center point in the scanner unit.

Acquired Ocular Motility Disturbances Associated with Orbital Pathology

Many patients with classic hyperthyroidism show no ocular muscle involvement; conversely, patients manifesting severe eye muscle restriction often have normal thyroid function but are considered to have a form of euthyroid myopathy. Progressive limitation of movement may occur many years after active thyroid disease, or it may be the presenting symptom of thyroid dysfunction. Orbital myositis is a nonspecific orbital inflammation involving one or more EOMs, with characteristic clinical and CT findings, and it is often very responsive to systemic corticosteroids. Patients with orbital myositis or other conditions may present with an onset of limitation of ductions (monocular movement in test fields of gaze) in one or both eyes, with variable signs of inflammation and proptosis.[15] These conditions include carotid-cavernous fistula, infectious cellulitis, lymphomas, retrobulbar masses such as cavernous hemangioma, and occasional metastatic disease. In patients with carotid-cavernous sinus fistula resulting from an abnormal communication between the carotid arterial system and the cavernous sinus, orbital venous congestion occurs, with subsequent swelling of the EOMs and mechanical interference with movement. There may also be an associated neurologic palsy, especially of the sixth cranial nerve. CT and MR imaging may demonstrate enlarged EOMs in these patients with generalized ophthalmopathy that will revert to normal after closure of the fistula. Other lesions of the cavernous sinus such as aneurysm may also be responsible for limitation of ductions.[15]

Brown's Superior Oblique Tendon Sheath Syndrome

In 1973, Brown described a clinical syndrome (superior oblique tendon sheath or Brown's syndrome) characterized by an impaired ability to raise the eye in adduction. Typically, the patient may have straight eyes or a hypotropia (one eye lower in the primary position). Brown further classified this condition into true and simulated syndromes.[169] True (congenital) Brown's syndrome includes only those patients with a congenitally short or taut superior oblique tendon sheath complex. Patients with simulated (acquired) Brown's syndrome acquire the clinical features of the syndrome secondary to a variety of etiologies. Most authors, including Brown, have postulated that acquired Brown's syndrome is primarily a disease of the tendon sheath–trochlear complex of the superior oblique muscle secondary to an inflammatory process of the adjacent tissues.

Normal ocular movement of the superior oblique muscle requires a loose sheath and free movement of the tendon in the sheath. When the eye is adducted, the primary action of the inferior oblique muscle is elevation. When the eye is elevated in the adducted position, the superior oblique muscle normally relaxes, causing its tendon to lengthen and slide freely through the trochlea. If the superior oblique muscle cannot relax or its tendon cannot lengthen, the eye cannot be elevated while adducted. This limitation of elevation in adduction simulates an inferior oblique palsy, although the pathologic process is postulated to be located primarily in the superior oblique complex. This restriction in the physiologic passage of the tendon through the trochlea may be permanent or occur on an intermittent basis in the acquired form.

In acquired Brown's syndrome, the symptoms and findings often are intermittent. Affected patients usually complain of intermittent double vision (diplopia) on upward gaze and sometimes a ''clicking'' sensation in the area of the trochlea when attempting to look up (Fig. 9-175).

The CT appearance may show abnormalities in the area of the trochlea in acquired Brown's syndrome (Figs. 9-175 and 9-176). One patient who had a history of head trauma showed significant thickening of the reflected portion of the superior oblique tendon in the involved eye (Fig. 9-175), which was confirmed at the time of surgery.[169] The association of acquired Brown's syndrome and rheumatoid arthritis has been well documented in the literature and may spontaneously disappear (Fig. 9-177).

The CT scan enables an evaluation of three features of the superior oblique muscle: (1) the angle that the reflected tendon makes with the medial wall of the orbit; (2) the thickness of the tendon; and (3) the density of the tendon compared with that of surrounding tissues.[170] Under normal circumstances, these characteristics are nearly equal in both eyes. The CT scan makes this comparison of both eyes possible in a manner that no other procedure allows. The angle of the reflected tendon may be altered by surgery. CT scanning may also be used to compare the angle of the reflected tendon with the clinical function of the superior oblique muscles and to determine damage to the trochlear region. However, in congenital Brown's syndrome, relatively little abnormality of the superior oblique tendon has thus far been demonstrated by CT scan.

Double Elevator Palsy

Double elevator palsy is a weakness of both elevators of the same eye (weakness of superior rectus and inferior oblique muscles is almost always congenital and is characterized by limited elevation through the entire upper field). There have been very few descriptions of CT findings in these patients, but two interesting cases showed a small superior rectus muscle, although the inferior oblique muscle could not be definitely identified (Fig. 9-178). Interestingly, one patient also had a large inferior rectus muscle. It is not known whether the size change is primary or secondary in nature. Congenital double elevator palsy must be differentiated from acquired conditions that cause a restriction in upward gaze, such as a blowout fracture of the orbital floor, a downwardly displaced superior orbital wall fracture with impingement on the globe, atypical Brown's syndrome, or endocrine myopathy with involvement of the interior rectus. This differentiation can be aided by forced duction testing and the radiographic findings. Patients with symptomatic double elevator palsy may require muscle-transposing surgery in the affected eye.

Other Causes

Myositis of the EOMs with proptosis and signs of orbital inflammation have also been reported with systemic lupus erythematosus; proptosis has been noted with dermatomyo-

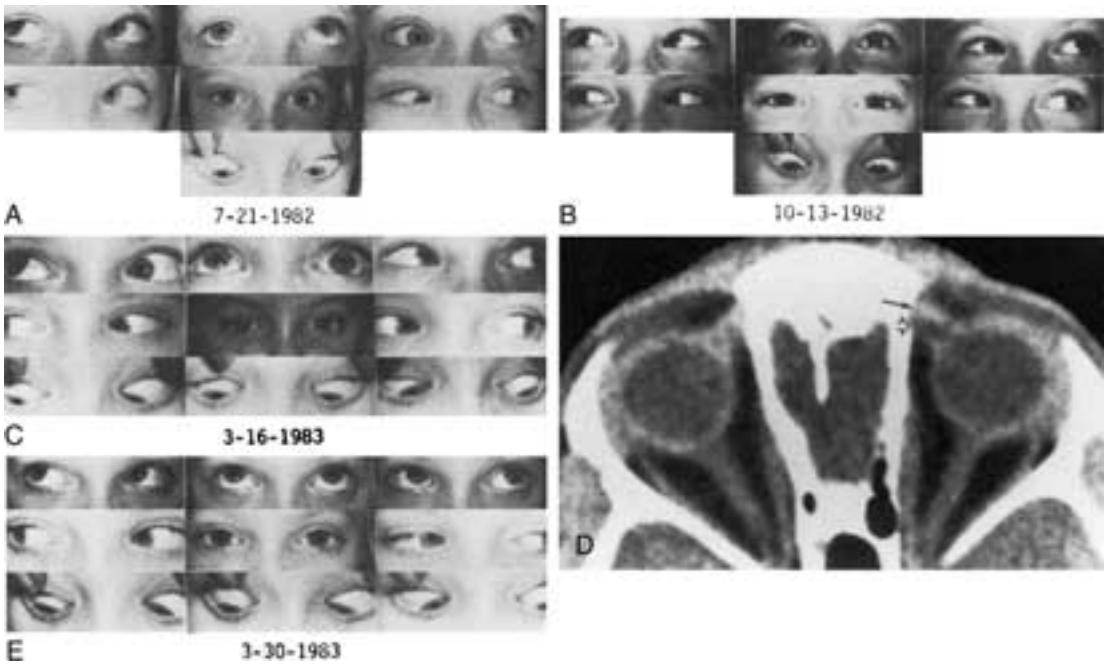
The eyes are normal in the primary (phoria) (*E*), right lateral (*B*), left lateral (*H*), down and right (*C*), downward midline (*F*), and down and left positions (*I*). However, in the upward midline (*D*) and up and left positions (adduction of right eye) (*G*), elevation of the right eye is lacking. As the eye is abducted, the level of elevation remains the same until the midline is reached (*D*, *G*), at which point full elevation is usually possible (*A*). When the eye is adducted nasally (*G*) from the primary position (*E*), the primary action of the inferior oblique muscle is elevation; thus, lack of elevation of the right eye during adduction (*G*), as in this patient, simulates paralysis of the right inferior oblique tendon, which is the hallmark of Brown syndrome. This actually represents ''pseudoparalysis'' because the cause is not dysfunction of the right inferior oblique muscle but rather inadequate relaxation of its antagonist, the right superior oblique muscle. **B**, Axial CT scan demonstrates thickening of the reflected portion of the right superior oblique tendon (*arrowhead*). The belly of the superior oblique muscle can be seen on each side (*hollow arrow*). **C**, Scan taken 1.5 mm higher demonstrates marked thickening of the reflected tendon (*arrow*). (From Mafee MF, Folk ER, Langer BG, et al.: Computed tomography in the evaluation of Brown syndrome of the superior oblique tendon sheath. Radiology 1985;154:691–695.)



VIEW IMAGE

FIGURE 9-176 **A**, Congenital Brown syndrome showing the eyes in various gazing positions. Note the markedly limited elevation of the right eye in the upward midline position (*top middle*), which is even more pronounced on adduction of the right eye (*top right*). **B**, Eleven months after tenotomy of the right superior oblique muscle, elevation is markedly improved on both adduction and abduction. **C**, Acquired Brown syndrome developed on the opposite side following trauma. Note the limited elevation of the left eye in the straight-up position (*top middle*) and during adduction (*top right*). **D**, Axial CT scan demonstrates slight thickening of the reflected portion of the left superior oblique tendon (*arrow*). The open arrow points to area of edema. **E**, After 2 weeks of steroid therapy, elevation is markedly improved on both adduction and abduction. (From Mafee MF, Folk ER, Langer BG, et al.: Computed tomography in the evaluation of Brown syndrome of the superior oblique tendon sheath. Radiology 1985;154:691–695.)

sitis. Other rare causes of EOM enlargement include Crohn's colitis, sarcoidosis, cysticercosis, and carcinoma metastatic to an ocular muscle. CT studies have shown large EOMs in many cases of acromegaly. The increased size appeared to be related to the disease duration but not to growth hormone levels. These muscle findings have been observed even in treated cases.

Tychsen and coworkers described a group of patients with tenderness over the trochlea and discomfort on movement of the eye. CT scans demonstrated a soft-tissue density in the area of the trochlea that was believed to represent a localized subtype of idiopathic orbital inflammation.[171]

Traumatic Injury of Ocular Muscles

Blowout Fracture

The classic blowout fracture involves the floor of the orbit, usually sparing the orbital rim (see Chapter 7). Frequently, orbital tissues are trapped in the fracture site and ocular motility disturbances have been ascribed to entrapment of one or both inferior EOMs, but clinical and surgical experience has not supported the entrapment etiology of restricted ocular movement in many cases. Early positive forced duction tests do not necessarily prove entrapment, and these disturbances may be the result of hematoma or inflammation. Soft-tissue damage may play a significant role in causing the typical findings of a blowout fracture.

Congenital Anomalies of the Extraocular Muscles

Congenital Syndromes

Ocular motility disturbances frequently occur in craniosynostosis syndromes, and the observed patterns of abnormal movement are characteristically predictable. This is particularly true for the craniosynostosis syndromes of Apert and Crouzon. The type of abnormal movement noted in these two groups may be affected by mechanical factors induced by abnormal anatomy but also may show abnormalities in the size of muscles and the location of insertion.

Apert's and Crouzon's syndromes usually show strabismus in the primary position in addition to the presence of a V pattern, with an exotropia in the up position and straight eyes or esotropia in the down position, thus producing a V configuration. Most patients also have an associated overaction of the inferior oblique muscles and show limitation of movement in the field of action of the superior rectus and superior oblique muscles. This pattern (V) of ocular muscle imbalance is not unique to patients with certain craniofacial anomalies; it is present in many patients without bony abnormalities. What is unparalleled is the frequency of craniosynostosis patients who manifest this abnormality.

Another somewhat unexpected and well-documented finding in vertical ocular muscle imbalance in craniosynostosis patients is abnormal insertion or structure of the muscle. A number of case reports have noted the apparent absence of vertically acting muscles at the time of surgery. Diamond and coworkers reported EOM anomalies (primarily of the inferior and superior rectus muscles) in 42% of their patients with craniofacial dysostosis. Orbital high-resolution CT scanning with thin cuts (1 to 1.5 mm) demonstrates changes in the location and/or the size of EOMs. Axial, coronal, and sagittal projections are useful in obtaining an accurate estimate of the degree of abnormality. Patients with gross limitation of movement are most likely to demonstrate CT scan abnormalities. This type of evaluation is indicated to plan appropriate surgical procedures if ocular motility surgery is contemplated or to plan alternatives if the ocular muscles cannot be located.

Noncomitant Strabismus Without Associated Malformations

A few studies have utilized CT analysis of the EOMs in normal subjects, with attention to variation in size and location. This method of analysis has also been used to evaluate the position or slippage of the muscles as the eyes move to different gaze positions.

In some types of routine comitant strabismus, the degree of horizontal deviation is noted to change when the patient looks up and down. If there is a significant difference in the amount of esotropia (or exotropia) in upgaze and downgaze, the patient is described as having an A or V syndrome. Since a V pattern has been observed in most patients with craniosynostosis deviation, it has been postulated that this may be caused or enhanced by an abnormal vertical insertion of the horizontal recti. Following this reasoning, some strabismus patients who manifested a V or A pattern of horizontal strabismus, but did not have any evidence of craniofacial anomalies, were evaluated by CT. One group of investigators noted some change in the position of the horizontal recti in these patients. Further data are necessary to understand these relationships.

Diagnostic imaging studies such as CT and MR imaging are invaluable tools to demonstrate orbital and EOM anatomy in cases of strabismus following trauma or surgery, or loss of rectus muscle function following strabismus surgery, retinal detachment surgery, or ocular trauma. Traumatic disruption of the orbital tissues can simulate a lost muscle by many different mechanisms: severed nerves, neuropraxia, muscle crush, muscle entrapment in an orbital wall fracture, muscle slippage, muscle fibrosis and contracture, edema, hemorrhage, and adhesions. When an EOM is surrounded by tissue edema, hemorrhage, granulation tissue, or scar tissue, there may not be sufficient contrast to differentiate muscle from adjacent tissue by CT and MR imaging. When diagnostic imaging fails to reveal the muscle in question, however, exploratory surgery should still be considered before the diagnosis of lost muscle is accepted.

ENDOSCOPY OF THE LACRIMAL DRAINAGE SYSTEM
SUMMARY

INTRODUCTION

Abnormalities of the nasolacrimal drainage system (NLDS) bring many patients to the eye clinic. The majority of these patients present with epiphora (tearing), with a smaller number presenting with swelling, discomfort, or a mass in the inferomedial orbit, the area of the lacrimal sac. Multiple diverse etiologies, intrinsic or extrinsic to the NLDS, may be responsible. To assess for causative factors, the clinician augments the clinical examination with specific clinical tests and/or an imaging referral to document the anatomy and functional capabilities, degrees and levels of patency of the NLDS itself, or to visualize the tissues extrinsic and adjacent to the NLDS.

This chapter will outline the various imaging tests available for such patients. Discussions of dacryocystogra-

phy, dacryoscintigraphy, computed tomography, magnetic resonance imaging, and CT and MR imaging with topically or cannula introduced contrast media or solutions will outline the indications for and relative benefits of these various tests in specific patient populations. Radiographic anatomy, the more common pathologic processes, and their correlative imaging will be discussed in reference to the patient presenting with epiphora or a mass lesion of the inferomedial orbit. Applicable surgical procedures and the more recent experience with alternative dacryocystoplasty or stenting procedures provide a perspective on the current treatment options available to the patient.

CONTRAST DACRYOCYSTOGRAPHY

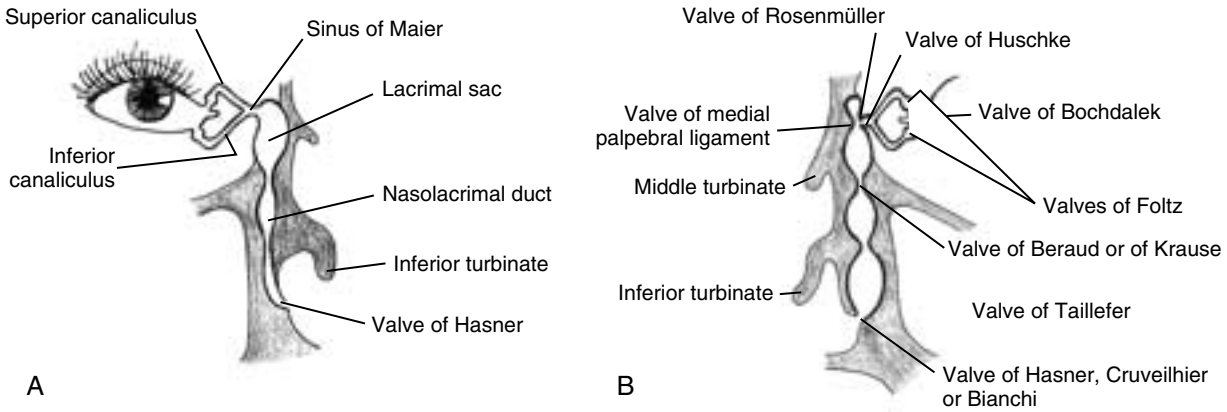
The radiographic evaluation of the NLDS by contrast dacryocystography (DCG) was first described by Ewing, and remains the definitive and usually the primary study in the evaluation of patients with tearing (epiphora) (Figs. 10-1[4] to 10-10).[1] Epiphora is a common cause of referral to the general ophthalmologist, and the treatment often requires surgery. DCG is capable of determining the patency of the canaliculi, lacrimal sac, and nasolacrimal duct. When disease is present, the site and degree of obstruction or stenosis or the presence of fistulae, diverticula, and concretions are well evaluated by DCG (Fig. 10-10).

Equipment

The equipment commonly used is illustrated in Figure 10-1. A dacryocystogram needle can be made by grinding off the sharp point of a 27-gauge lymphangiogram needle; the tip should be rounded and polished so that no metallic burrs remain. An alternative to this needle is a tapered catheter, as described by Iba and Hanafee,[2] made from no. 18 Teflon tubing, or commercially available Rabinov sialography catheters with a fine metallic cannula of 0.016 inch (27 gauge) diameter (Cook, Inc, Bloomington, Indiana). A punctal or lacrimal dilator (sharp or blunt Nettleship dilator) is also utilized, and for simultaneous injection and visualization of bilateral studies, a Y-connector may be helpful.

Contrast Materials

A variety of opaque contrast media have been used. Ewing used bismuth subnitrate in liquid petrolatum. Since then, ethiodized oil (ethiodol), iodized oil (lipiodol), and iophendylate (Pantopaque) have also been used.[1, 3–5] Such oil-based contrast media, (e.g., ultrafluid lipiodol) were felt to better fill the NLDS than water-soluble agents, were less irritating, and were undiluted by tears, offering better opacification. Such contrast entered the NLDS at negligible pressure, minimizing the chances of extravasation. However, oil-based agents have disadvantages in the NLDS. First, if extravasated, oily contrast can remain in the soft tissues for many years, inciting a granulomatous inflammatory response.[6] Second, oily opaque material is not completely miscible with tears and can fail to fill or coat the entire NLDS, limiting diagnostic capabilities. Third, oily



VIEW IMAGE

contrast is more viscous than tears and often requires heating (especially with iodized oil) to reduce its viscosity before being injected.[7] If not heated, oily material requires a greater injection pressure than aqueous contrast material. Physiologic aqueous solution in the form of methylglucamine diatrizoate 40% (methylglucamine iodipamide 20%, Sinografin) was proposed by Sargent and Ebersole[6] as an excellent dacryocystographic contrast agent that was nonirritating, water soluble, miscible with tears, and similar in viscocity and pH to tears. Nonionic or lower osmolar aqueous solutions provide variable levels of iodine concentration and decreased viscosity, and are preferred for use when combining dacryocystography with digital subtraction techniques (see the section on Digital Subtraction (Macro) Dacryocystography). Munk et al.[8] noted some patient discomfort (a burning sensation) with sinografin and the nonionic solutions of 300 mg iodine per milliliter. Lipiodol offered the highest level of comfort and was the only ''tasteless'' solution. All the aqueous solutions have a disagreeable or mildly unpleasant taste but are safe to swallow.

Radiographic Techniques

Since the original description of Ewing,[1] many radiographic techniques for DCG have been described. The following are the more commonly used techniques:

- Macrodacryocystography, which uses a magnification (two and a half diameters optimum) technique after van der Plaat's description of radiographic magnification procedures.[9, 10]
- Kinetic DCG, which uses a cinematography format for evaluating the anatomy and function of the nasolacrimal apparatus.[11, 12]

FIGURE 10-3 *Continued.* **D**, Anatomic variant with the left common canaliculus draining into the fundus of the lacrimal sac. **E**, Left common canaliculus empties into the lacrimal sac more inferiorly than usual. The left lacrimal sac is mildly dilated, with slight delay of drainage into the nasolacrimal duct.

- Distention DCG, which involves plain radiographs that are obtained during injection of the contrast material to better fill (distend) the NLDS.[2]
- Intubation macrodacryocystography, which combines distention DCG and macrodacryocystography.[13]
- Subtraction DCG, which combines intubation macrodacryocystography with a standard photographic subtraction technique.[14, 15]
- Tomographic DCG, which uses complex motion tomography to offer finer detail of the nasolacrimal apparatus. Thin-section images can be obtained in the frontal and lateral planes with improved detail compared to the above techniques[16] (Figs. 10-4 to 10-6).
- Digital subtraction DCG, which combines the techniques of dacryocystography with digital subtraction fluoroscopic capabilities.[17, 18] With the availability of higher-resolution digital capabilities, this technique has become the routine dacryocystographic study and is described separately in this chapter.

Injection Techniques

The study is performed with the patient supine on the examination table, and initial preliminary films are obtained to ensure patient positioning and image quality. The procedure is not uncomfortable, and in many patients no topical anesthetic is necessary. However, to make the patient more relaxed and to decrease blinking and lacrimation, one may instill into the conjunctival sac a very short-acting topical ophthalmic anesthetic (e.g., 0.5% proparacaine [Ophthaine]). Oxybuprocaine 0.4% is a very short-acting topical anesthetic that does not require shielding of the eye following the procedure, thus making it especially advantageous for bilateral studies. Approximately 2 ml of the radiopaque contrast material is drawn into a small syringe, which is then connected to the lacrimal cannula and tubing, and the system is cleared of any air bubbles. The inferior punctum is then dilated with a lacrimal dilator, with the lower lid slightly everted and with minimal lateral traction to help stabilize the punctum. To avoid damage (false passage) to the canaliculus, the dilator, and subsequently the cannula, are positioned initially perpendicular to the lid margin and then rotated 90° horizontally to be directed medially along the horizontal component of the canaliculus (with the lower lid stretched laterally). The lacrimal sac and medial canthus are then palpated to detect any mass lesion, fullness, or tenderness and to express any fluid present in the sac through the punctum or into the nose. Ideal procedure includes pre-DCG irrigation and careful expression of the lacrimal sac to flush out accumulation of thickened mucus within the duct system. Failure to irrigate the nasolacrimal duct system (NLDS) or express the lacrimal sac contents may lead to interpretive difficulties, including improper estimation of the size of the lacrimal sac or misdiagnosis of obstructions proximal to a stenosing lesion due to the retained secretions.[19] Residual fluid in the sac causes oil-based contrast media to form globules, giving a false impression of a polycystic sac or diverticula.[9] The lacrimal cannula is then

Copyright © 2003, Mosby, Inc. All rights reserved.

placed into the inferior punctum just far enough to remain stable during the study, and the tubing is taped to the patient's face. Care should be taken to avoid a common error, which is placement of the cannula too far into the inferior canaliculus. Frontal projection images approximating the Water's projection (40° occipitomental projection) are used to bring the nasolacrimal duct parallel to the imaging plane in an attempt to eliminate any distortion of the nasolacrimal duct. In this projection, the inferior orbital rim is approximately at the level of the junction of the middle and upper third of the nasolacrimal duct.[9] A coned occipitomental view is also obtained, centered midline at the inferior orbital margin. The injection is then made, and films are immediately obtained. If distention DCG, intubation DCG, or digital subtraction DCG is used, the films are obtained during the injection. Initial or subsequent cannulation of the superior punctum may be appropriate when there is difficulty with cannulation of the inferior punctum or when further assessment is required following the initial injection of the inferior punctum. A delayed upright film should be taken, especially if obstruction is suspected, to assess possible delayed drainage into or through the inferior drainage system.

The decision to perform specific unilateral or routine bilateral DCG varies with the individual or institutional philosophy. Routine bilateral DCG may be justified by the

relative ease of the procedure; the lack of additional radiation, since the contralateral orbit is frequently included in the field of study; and the frequent finding of abnormalities in the clinically ''asymptomatic'' side.[20] Bilateral simultaneous injection, using a Y-connector, allows comparative flow characteristics through the NLDS. Other centers restrict the cannulation and visualization to those NLDSs that are symptomatic, eliminating any potential for iatrogenic insult to the noninvolved tear duct system.

DIGITAL SUBTRACTION (MACRO) DACRYOCYSTOGRAPHY

In contrast to intubation macrodacryocystography using a serial film changer, digital subtraction dacryocystography (DS-DCG) allows, under fluoroscopic control, proper positioning and subsequent real-time imaging during the introduction of contrast medium. Images are usually taken every 1 to 2 seconds and can be terminated as soon as

Right cicatrized lacrimal sac (*straight arrow*). Left lacrimal sac mucocele (*curved arrow*). Stenosis also is present in the left inferior canaliculus (*thin arrow*). **H**, Stenosis at the valve of Hasner (*short arrows*), with distention of the distal right nasolacrimal duct. Mild stenosis in the left common canaliculus (*thin arrow*) with no reflux to the superior canaliculus.

Illustration continued on following page

patency or obstruction is defined. Fewer images (4 to 6) are usually acquired than for conventional DCG (6 to 10 images).[17] Digital adjustment of the data provides the most desired image quality on the ''hard copy'' film. The subtraction image is also digital, avoiding the time-consuming process of conventional photographic subtraction. The radiation dose to the lens is less in DS-DCG than in conventional DCG. Lead eye protection can reduce lens dosage, with further reduction achieved by noting early ductal patency using the real-time imaging capability of DS-DCG.[18, 21] The use of a carefully collimated high-kilovoltage primary beam; lead eye shields, which do not compromise the diagnostic quality of the study (placed lateral and anterior to the NLDS); and 30° oblique lateral projections for simultaneous bilateral DCG are simple measures that decrease by 97% the lens dosage required with conventional techniques. With these techniques, the radiation dosage for bilateral DCG can be limited to less than 1 mGy (1 mGy = 100 mrad) to the lens.[21] For conventional DCG, the patient lies supine, and the x-ray source is anterior to the patient. With DS-DCG the patient is also supine. However, the x-ray source is posterior to the patient, so that the cranium acts as a ''radiation shield'' to the lens. Galloway et al.[17] found the actual lens radiation dose/exposure to be 13 times greater for conventional DCG than for DS-DCG (270 vs. 20 mrad), with the total lens radiation dose per study (six exposures each) being 1644 versus 126 mrad. King and Haigh's[18] study had a mean radiation dose/DS-DCG run of 0.68 mSv compared with 1.53 mSv (l mSv = 100 mrem) for conventional two-film DCG, with the latter patients studied in the uncommon occipitomental position, and therefore having a lower reading than for the mentooccipital position usual for conventional DCG. Repeat studies needed as a result of suboptimal radiographic exposure factors were also obviated. Similarly, the ability to visualize the early flow of contrast medium through the canaliculi and upper drainage system obviates the need to repeat studies in which reflux into the conjunctival sac obscures information of canalicular patency.

In the early phase of injection, reflux can be minimized by an initial slow injection rate. Subsequently, the rate can be

Copyright © 2003, Mosby, Inc. All rights reserved.

increased to achieve greater sac distention or to overcome resistance caused by partial obstruction.[17] The ability of DS-DCG to clearly demonstrate the upper drainage system, especially the common canaliculus, further reduces the relative radiation exposure of conventional DCG by obviating the need for tomographic DCG. DS-DCG has also dramatically decreased the need for lateral radiographic images. In the majority of studies, a single dynamic injection is required. In those departments where lacrimal imaging is infrequently performed, the advantages of DS-DCG become more apparent in both radiation reduction and study quality.[18]

With the newer digital units, spatial resolution is superb, approaching that of conventional radiography, while the contrast resolution of digital imaging is markedly superior to that of conventional imaging. The immediate viewing (or reviewing) of DS-DCG images significantly reduces the proportionate length of the study, allowing more efficient use of time for the radiologist and the patient. The increased contrast sensitivity of digital imaging allows for greater flexibility of choice of contrast agents, with water-soluble agents being preferred because of their lower viscosity, greater miscibility with tears, and easier flow through the NLDS. These agents usually require smaller volumes and have lower iodine content than the agents used for conventional DCG. For appropriate DS-DCG images, the patient must be fully cooperative, and be able to lie still and follow instructions, although manipulation of the computed data can offset minor degrees of movement. The use of topical anesthetic and the choice of catheters and their placement within the canaliculus are similar to those of conventional DCG.

Inclusion of a late (delayed) image, after the patient has been in the upright position for 5 minutes, increases the sensitivity of DCG or DS-DCG, with the specific intention to assess for failure of gravitational drainage of contrast medium from the nasolacrimal duct system (NLDS). This delay also allows DCG and DS-DCG, more anatomically orientated imaging procedures, to offer a physiologic component to the procedure, augmenting the value of DCG and DS-DCG in the evaluation of patients with functional nasolacrimal duct obstruction (FNLDO).[22] (In the section on Dacryoscintography, see also Incomplete Obstruction and Functional Nasolacrimal Duct Obstruction.) FNLDO is diagnosed if there is poor emptying, with residual contrast material present in the lacrimal sac or nasolacrimal duct on the delayed image. In the normal patient, contrast medium almost immediately disappears from the NLDS with the patient placed in the upright position. Issues with viscosity and surface tension may affect contrast drainage. Oil-based contrast may be more easily detected as small droplets within the duct system.[22] Water-soluble contrast, although safer, may be partially absorbed by the epithelium of the NLDS during the delayed period. Although Zinreich et al.[23] have attempted contrast DCG by simply placing the radiographic contrast agent into the conjunctival sac, the display of anatomic structures is less detailed than with DCG using cannulation despite the sensitivity of digital subtraction imaging. The hope that such a topically applied contrast

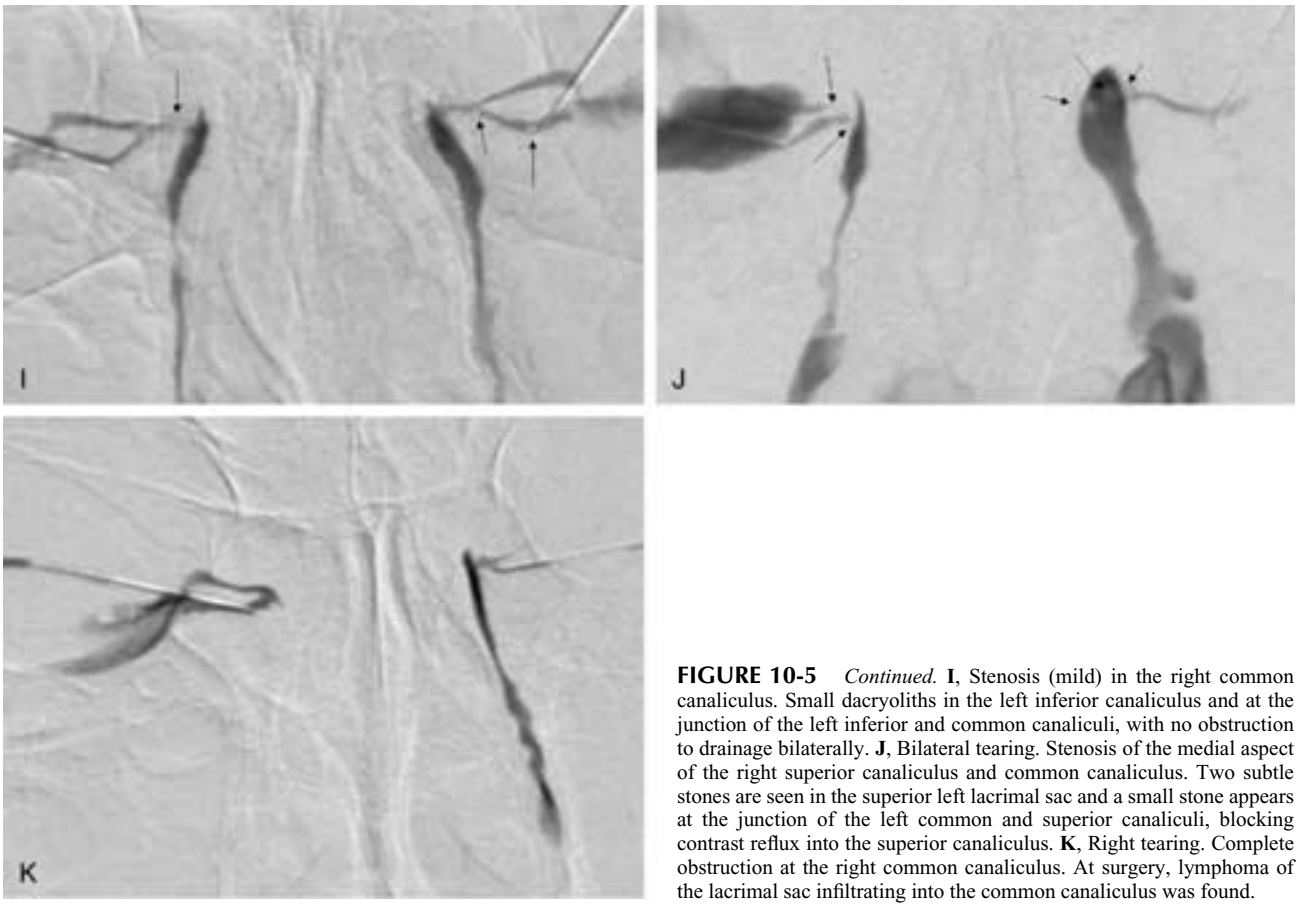

FIGURE 10-5 *Continued.* **I**, Stenosis (mild) in the right common canaliculus. Small dacryoliths in the left inferior canaliculus and at the junction of the left inferior and common canaliculi, with no obstruction to drainage bilaterally. **J**, Bilateral tearing. Stenosis of the medial aspect of the right superior canaliculus and common canaliculus. Two subtle stones are seen in the superior left lacrimal sac and a small stone appears at the junction of the left common and superior canaliculi, blocking contrast reflux into the superior canaliculus. **K**, Right tearing. Complete obstruction at the right common canaliculus. At surgery, lymphoma of the lacrimal sac infiltrating into the common canaliculus was found.

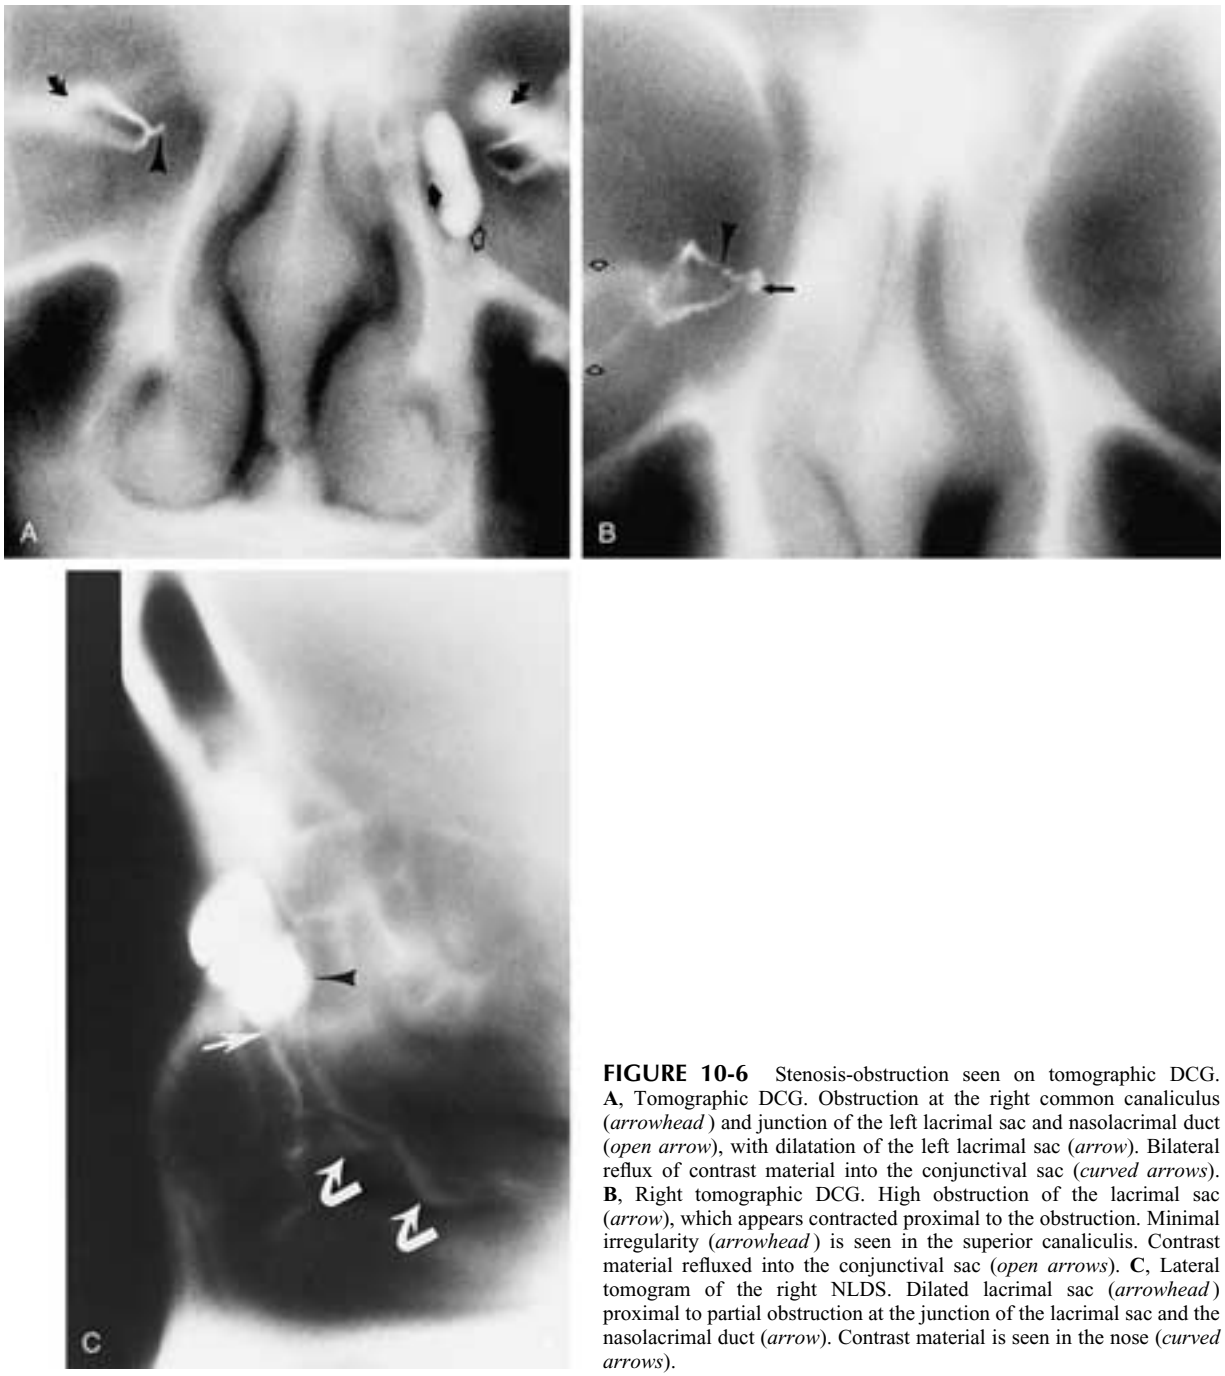

FIGURE 10-6 Stenosis-obstruction seen on tomographic DCG. **A**, Tomographic DCG. Obstruction at the right common canaliculus (*arrowhead*) and junction of the left lacrimal sac and nasolacrimal duct (*open arrow*), with dilatation of the left lacrimal sac (*arrow*). Bilateral reflux of contrast material into the conjunctival sac (*curved arrows*). **B**, Right tomographic DCG. High obstruction of the lacrimal sac (*arrow*), which appears contracted proximal to the obstruction. Minimal irregularity (*arrowhead*) is seen in the superior canaliculis. Contrast material refluxed into the conjunctival sac (*open arrows*). **C**, Lateral tomogram of the right NLDS. Dilated lacrimal sac (*arrowhead*) proximal to partial obstruction at the junction of the lacrimal sac and the nasolacrimal duct (*arrow*). Contrast material is seen in the nose (*curved arrows*).

VIEW IMAGE

DCG may allow the physiologic advantage of dacryoscintigraphy to be combined with the anatomic detail of cannulated DCG has yet to be fulfilled. The main acceptance of this technique is in its application to CT-dacryocystography or MR-dacryocystography techniques.

CLINICAL TESTS

Before referral for DCG, most patients are seen by an ophthalmologist, who performs a number of tests to assess epiphora.

Probing

Multiple calibers of fine flexible probes (Bowman probes 0000 to 0) may be used to ''palpate'' the nasolacrimal drainage lumen. Such probes can be passed to a ''hard stop'' representing the medial wall of the lacrimal sac. Slight withdrawal and downward angulation of the probe may allow entry into the nasolacrimal duct. A feeling of ''give'' or loss of resistance may be felt as the probe passes through the valve of Hasner. The upper drainage system is considered patent if a No. 0 probe passes through to the medial wall of the lacrimal sac.[24]

Irrigation

Standard lacrimal cannulation and irrigation are performed using saline solution. The patient is usually inclined forward, in a sitting position, to allow the irrigating solution to be readily assessed exiting from the nostrils. False-negative or false-positive tests may partly result from the variable ability (subjective) of the patient to detect the presence of saline entering the nasopharynx. A small amount of fluoroscein may be added to the saline to assist in the detection of patency of the drainage system. Syringing of the lacrimal system correlates poorly with DCG[25] and shows an 18% discordance with dacryoscintigraphy (DSG)[26] in detecting obstruction.

Dye Tests

Jones 1 Test

The fluoroscein 2% dye test (the primary dye test) detects functional obstruction, that is, defines the inability of the drainage apparatus to pump tears from the eye to the nose.[27] Two drops of dye placed into the conjunctival cul de sac should reach the nasal cavity within 1 to 3 minutes (positive test). It should be noted that in the Jones tests, a normal result is referred to as a positive test, unlike in most imaging examinations. The dye may be retrieved on a nasal applicator or confirmed by nose blowing or by nasal irrigation with saline.

FIGURE 10-8 *Continued.* **E**, Superior canalicular injection. Mild stenosis (*thin arrows*) of the medial common canaliculus and the medial aspect of the right superior and inferior canaliculi. Obstruction of the distal right lacrimal sac (*short arrow*). Narrowed segment (*curved arrow*) of the lacrimal sac is due to fibrosis. **F**, Distended lobulated left lacrimal sac (mucocele) with outlet obstruction (*short arrow*). Severe stenosis (*thin arrows*) of the left common canaliculus (with focal dilatation) and inferior and superior canaliculi medially. Cicatrized right lacrimal sac (*curved arrow*). **G** and **H**, Bilateral tearing. **G**, Irregular dilated right superior canaliculus and stenosis at the junction of the common canaliculus and lacrimal sac, with contrast refluxing into the conjunctival sac. Obstruction at the medial aspect of the left inferior canaliculus (*arrows*), with contrast refluxing into the conjunctival sac. **H**, Repeat injection. The right cannula was moved closer to the punctum to better visualize the stenosis in the medial aspect of the right inferior canaliculus (*arrow*). Left injection through the superior punctum shows no obstruction to drainage. No reflux into the obstructed inferior canaliculus (*arrow*).

Jones 2 Test

If the Jones 1 test is negative (no dye reaches the nasal cavity), the Jones 2 test is performed by irrigating the NLDS with a saline solution (1 ml) after the conjunctival application of fluoroscein dye has been irrigated out of the conjunctival sac.[27]

1. Lack of fluid entering the nose is evidence of complete obstruction in the drainage system (negative test).
2. The presence of clear saline in the nasal cavity implies that the fluoroscein did not reach the lacrimal sac. The test is negative (abnormal). The canaliculi may be open, but they are not functioning, and the abnormality is localized to the upper NLDS.
3. Deeply stained fluid entering the nasal cavity implies that the fluoroscein reached the lacrimal sac physiologically but did not drain any further. The test is positive (the lacrimal pump and canaliculi are functioning, so that the lacrimal sac fills). There is incomplete obstruction of the nasolacrimal duct.

If both the Jones 1 and 2 tests fail to detect fluoroscein in the nasal cavity (negative tests), the lacrimal system is irrigated with fluoroscein to confirm total obstruction.[28]

Schirmer's Test

Schirmer's test is a measure of the eye's ability to produce tears in response to an external stimulus and can be estimated by the amount, in millimeters, of filter paper wetting by lacrimal fluid in 5 minutes. A dry eye may intermittently produce a large amount of tears, simulating epiphora. The test can differentiate hyposecretion and pseudoepiphora from normal secretions.[27]

Valsalva DCR Bubble Test

The Valsalva DCR bubble test offers confirmation of patency of a dacryocystorhinostomy site. A drop of saline is placed at the inner canthus, and the patient is asked to perform the Valsalva maneuver. The formation of a bubble

Copyright © 2003, Mosby, Inc. All rights reserved.

in the region of the punctum indicates a positive test.[29] Again as in the Jones test, the normal test is referred to as positive.

INDICATIONS FOR DACRYOCYSTOGRAPHY

DCG is indicated to investigate patients with epiphora after the clinical examination suggests a mechanical obstruction. Campbell[9] outlined the three fundamental principles in interpretation of DCG: (1) to describe the level of the obstruction, (2) to state whether the obstruction is complete or incomplete, and (3) to determine the cause of the obstruction. The suspected obstruction may be associated with various clinical conditions, including congenital obstructions, supernumerary canaliculi, lacrimal fistula or diverticula, concretions (dacryoliths), neoplastic or inflammatory processes, or posttreatment changes. When there is clinically assessed chronic obstruction, surgical or interventional treatment is indicated and DCG should offer maximum information to allow the appropriate procedure.

SURGICAL PROCEDURES FOR EPIPHORA

The most common surgical procedure for epiphora is a dacryocystorhinostomy (DCR), in which the medial wall of the lacrimal sac is opened into the nasal cavity, with specific attention being devoted to appropriate removal of adjacent bone (osteotomy) and suturing of the lacrimal sac and nasal mucosal flaps.[30] DCR is the procedure of choice to treat epiphora secondary to obstruction or severe stenosis of the distal lacrimal sac and the nasolacrimal duct. Stenoses or occlusion within the upper drainage system, proximal to the lacrimal sac, may require placement of fine stents (silastic or rubber) within the canaliculi to complement the DCR. Alternatively canaliculo-DCR may be performed, with resection of a canalicular stenotic segment and anastomosis to the lacrimal sac and incorporation into the DCR.[31] These stents are placed on a temporary basis. Construction of a conjunctival tract with insertion of permanent glass tubes (Pyrex) to bypass an occluded canaliculus (conjunctival DCR) has long-term implications for care and maintainance.[32] A limited canthocystostomy (lacrimal sac opened into the conjunctival fornix) procedure may be performed when the lacrimal sac and lower NLDS are intact and

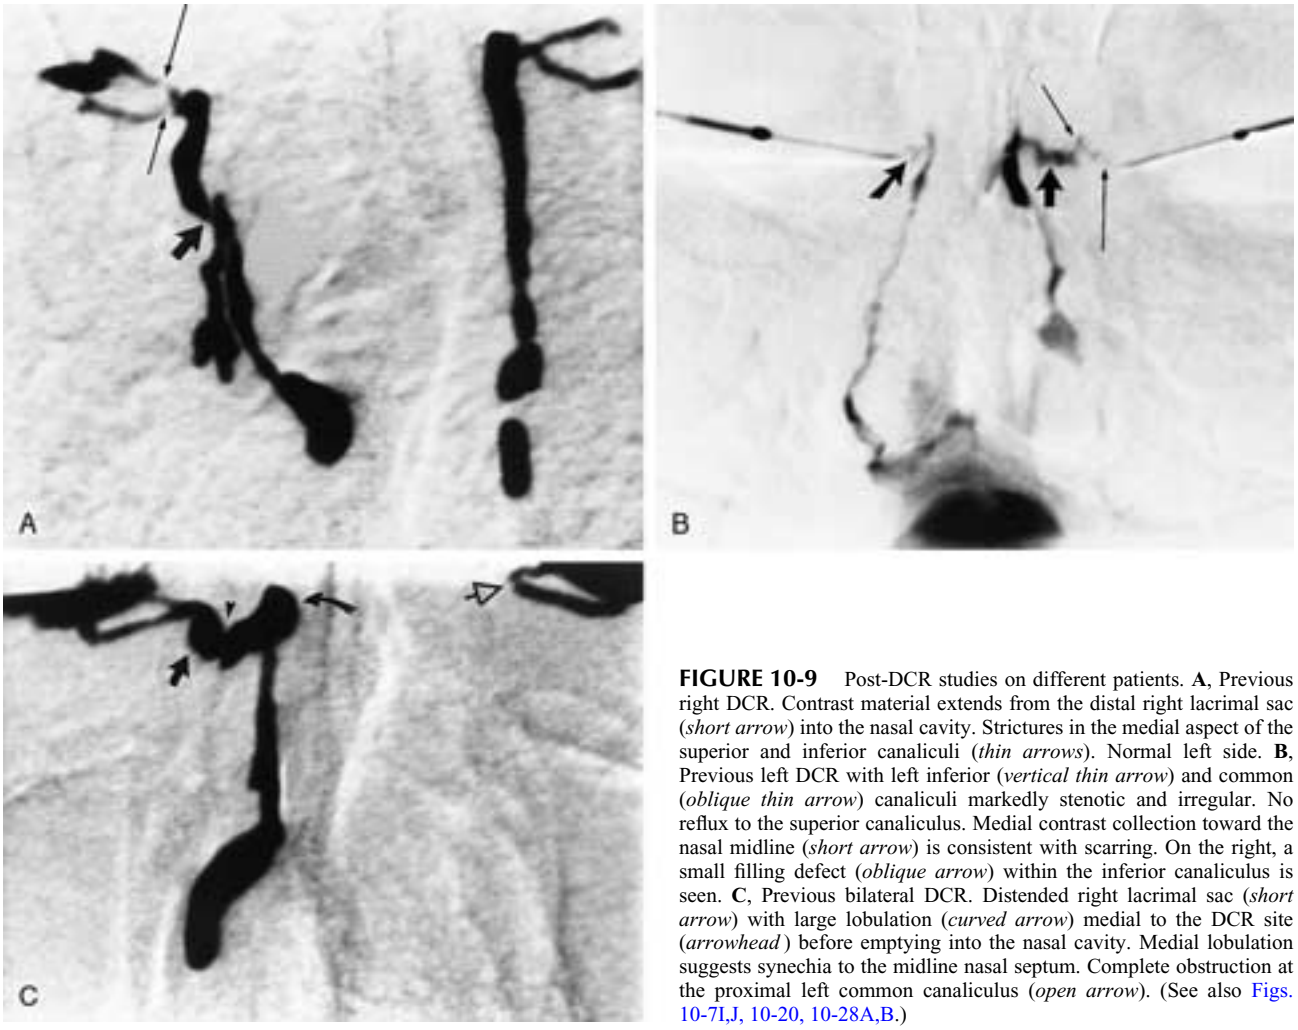

FIGURE 10-9 Post-DCR studies on different patients. **A**, Previous right DCR. Contrast material extends from the distal right lacrimal sac (*short arrow*) into the nasal cavity. Strictures in the medial aspect of the superior and inferior canaliculi (*thin arrows*). Normal left side. **B**, Previous left DCR with left inferior (*vertical thin arrow*) and common (*oblique thin arrow*) canaliculi markedly stenotic and irregular. No reflux to the superior canaliculus. Medial contrast collection toward the nasal midline (*short arrow*) is consistent with scarring. On the right, a small filling defect (*oblique arrow*) within the inferior canaliculus is seen. **C**, Previous bilateral DCR. Distended right lacrimal sac (*short arrow*) with large lobulation (*curved arrow*) medial to the DCR site (*arrowhead*) before emptying into the nasal cavity. Medial lobulation suggests synechia to the midline nasal septum. Complete obstruction at the proximal left common canaliculus (*open arrow*). (See also Figs. 10-7I,J, 10-20, 10-28A,B.)

FIGURE 10-10 Shortened left nasolacrimal duct. Contrast material enters the left nasal cavity (*arrow*) more superiorly than usual (compare with the right side). There was previous resection of a left maxillary sinus neoplasm.

patent.[9] A canthoplasty (lateral) with resection and tightening of the preseptal and pretarsal orbicularis muscle may correct abnormal positions of the lid and allow tears to enter the punctum.

The increasing trend of minimally invasive surgical techniques, combined with the advancing technology of endoscopic visualization, has also been applied to the lacrimal patient. Endoscopic dacryocystoplasty (endonasal DCR), utilizing an endonasal endoscope to make an anastomosis (using traditional bone-removing instruments or a laser) between the lacrimal sac and the nasal cavity, circumvents the external approach (Toti's operation). With no external scar, the endoscopic approach offers better cosmesis. There is preservation of lacrimal pump function of the orbicularis oculi muscle, the presaccal fibers, the medial canthal tendon and their osseous supporting structures by approaching the lacrimal sac from the nasal cavity.[33–35] Compared to external DCR, endonasal DCR is less traumatic and offers minimal morbidity, less intraoperative bleeding, a shorter operative time, and a low complication rate.[36] Endoscopic DCR is a more difficult procedure to learn, is more technically challenging, and has the disadvantage of a smaller anastomotic opening and a higher recurrence rate of epiphora. Bone removal by drilling or by laser may cause overheating and increase the risk of postoperative fibrosis and closure of the lacrimal window.[35] As for external DCR, scarring of the ostium and errors in ostium location are the major reasons for surgical failure.[37] Epithelial anastomosis and continuous fluid flow are necessary for maintaining a patent surgical rhinostoma. For this purpose, a silicone stent is placed and is usually kept in place for at least 2 months.[36] Conversely, Kong et al.[38] suggest removal of the silicone tubes before 8 weeks to prevent granuloma formation and closure of the osteotomy site. Premature tube dislodgement may be associated with surgical failure.

Microendoscopy of the NLDS, endocanalicular and translacrimal DCR,[39] and fiberoptic laser probing are less frequently used surgical procedures for the treatment of lacrimal sac and nasolacrimal duct obstruction. Translacrimal and endocanalicular laser DCR techniques offer the advantage of less surgical dissection. The laser energy is directed away from the eye, avoiding the risks of laser injury to the globe that may occur with laser-assisted endonasal DCR.[39, 40] Thermal injury of the lacrimal sac may increase postoperative scarring and reduce patency.[41] (See also the section on Endoscopy of the Lacrimal Drainage System later in this chapter.)

THE NORMAL DACRYOCYSTOGRAM

Anatomy

The lacrimal system consists of the inferior canaliculus, superior canaliculus, common canaliculus, lacrimal sac, and nasolacrimal duct (Figs. 10-2 to 10-4). Tears from the conjunctival sac enter the punctum of both the inferior and superior canaliculi approximately 6 mm lateral to the medial canthus, briefly travel through a 2 mm vertical segment, and then turn abruptly medially to continue in the longer (7 to 10 mm) horizontal canalicular segment. There is a slight dilation, the ampulla, at the junction of the vertical and horizontal components of each canaliculus.[42] The superior and inferior canaliculi merge to form the common canaliculus (common ampulla) and enter a small diverticulum of the lateral wall of the lacrimal sac, the sinus of Maier. Occasionally the canaliculi enter the sinus of Maier separately. The upper canaliculus is slightly shorter and straighter than the lower, and the canalicular diameter is 0.5 mm, with a punctal diameter of 0.3 mm. The thin, elastic walls of the canaliculi allow the canaliculi to be dilated three times their normal diameter or to be straightened by lateral tension on the eyelid, an anatomic feature of significance for probing or instrumentation.[42] The punctal region is relatively avascular and therefore paler than adjacent tissues. This contrast is accentuated by lateral tension on the lid margin, helping to locate a stenosed punctum. The normal close contact between the puncta and the conjunctival tear fluid is essential (and should be noted for normal function) since the canaliculi fill by capillary extraction.

The common canaliculus is 1 to 5 mm in length and terminates medially through flaps of mucosa created by the acute angle with which the sinus of Maier enters the lacrimal sac. The superior flap is called the valve of Rosenmüller, and the inferior flap is called the valve of Huschke. The canaliculus enters the lateral aspect of the nasolacrimal sac just above the junction of its upper and middle thirds (i.e., 3 mm from the dome of the sac).[27]

In 1911, Schaeffer[43] described three different ways in which the canaliculi communicate with the lacrimal sac: (1) they can drain through a common canaliculus; (2) they can empty separately into a diverticulum of the lacrimal sac (sinus of Maier); or (3) in rare cases, they can empty separately into the lacrimal sac, with no common canaliculus or diverticulum present. Variations in the configuration

VIEW IMAGE

FIGURE 10-11 Forms of canalicular connection to the lacrimal sac. **Type A**: Upper and lower canaliculi join the common canaliculus. **Type B**: Upper and lower canaliculi join at the lacrimal sac wall to form a common opening. **Type C**: Upper and lower canaliculi enter the lacrimal sac separately. (Adapted from Yazici B, Yacizi Z. Frequency of the common canaliculus. A radiological study. Arch Ophthalmol 2000;118:1381–1385.)

of the common canaliculus have been noted. Approximately 90% of individuals have the typical configuration, that is, a common canaliculus clearly defined between the merged inferior and superior canaliculi laterally and the entry point into the lateral wall of the lacrimal sac medially.

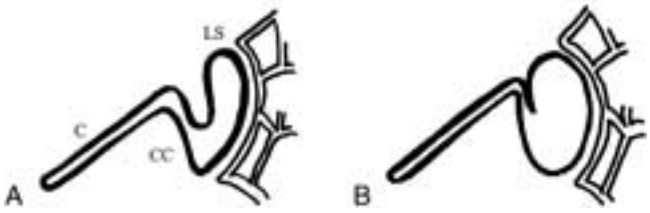
For the 10% of the population for whom a common canaliculus is not present, there has been no clear description of how the canaliculi terminate. Jones and Wobig[27] reported that in 10% of individuals, the canaliculi actually open separately into a ''sinus of Maier,'' which in turn opens into the tear sac, implying only one common internal opening, also celled the inner punctum, into the tear sac. The term *sinus of Maier* is somewhat confusing since it has been used to describe three different anatomic entities: (1) the common canaliculus itself; (2) the terminal dilation of a common canaliculus; and (3) the lacrimal sac diverticulum into which the canaliculi open separately.[27, 42, 44] Yacizi and Yacizi[44] propose a functional term, *common opening*, to describe the configuration in which the common canaliculus is absent and the canaliculi unite at the sac wall and drain by one ostium. In a smaller number of patients, the upper and lower canaliculi drain separately and distinctly into the lacrimal sac.

In a recent study of 341 digital subtraction macrodacryocystograms on patients with obstructive epiphora, Yacizi and Yacizi[44] noted that 94.1% had the typical common canaliculus configuration (type A). In this study, 3.8% had an absent common canaliculus, with the lower and upper canaliculi united at a common opening in the lacrimal sac wall and draining into the lacrimal sac through this opening (type B). In only 2% of the studies did the upper and lower canaliculi drain separately into the lacrimal sac (type C) (Fig. 10-11).

In type B, the upper and lower canaliculi joined at a narrow angle at the lacrimal sac wall for a common opening. This pattern was unlikely to be confused with type C since the type C canaliculi maintained nearly parallel courses as they approached and maintained separate openings into the lacrimal sac. The authors[44] emphasize analysis of the early images of canalicular filling before a distended lacrimal sac may obscure a short common canaliculus and resemble a type B or type C pattern. There is no evidence that the presence or type of canalicular drainage affects the clinical course of nasolacrimal duct obstruction. Nasolacrimal duct obstruction, with resultant lacrimal sac distention, causes kinking of the common canaliculus (and probably of the superior and inferior canaliculi in type B and C configurations) due to compression by the lacrimal sac and may better explain further sac enlargement. Anatomic configurations have surgical implications for planned probings or silicone intubations at the time of DCR or for repairs of traumatized (lacerated) canaliculi to prevent the creation of false canalicular passages.

Review of the functional anatomy of the lacrimal outflow system at the junction of the common canaliculus and lacrimal sac may also be warranted. Mucosal folds at the superior and inferior borders of the common canaliculus–lacrimal sac junction have been described and respectively named the valve of Rosenmüller and the valve of Huschke. These valves have been seen or described inconsistently and occasionally have been omitted in the literature. Only the Hasner valve at the distal nasolacrimal duct has been shown to be a functional barrier to retrograde flow or reflux of fluid. However, the belief that the Rosenmüller valve prevents tear reflux from the lacrimal sac to the common canaliculus has persisted as the only explanation for the lack of reflux of lacrimal sac contents. The theory holds that the valve may become tighter with edema, inflammation, and distortion related to dacryocystitis, explaining the difficulty of cannulating the lacrimal sac in cases of dacryocystitis, dacryocystocele, or acute dacryocystic retention.[45]

Tucker et al.[46] have hypothesized that the Rosenmüller valve alone may be insufficient to explain the functional valve mechanism and offer an alternative finding and theory from their study of casts of lacrimal outflow systems. A consistent canaliculi configuration of an initial posterior vector at the level of the eyelids, followed by an anterior vector after passing posterior to the medial canthal tendon, with continuation in this anterior direction to enter the lacrimal sac at an acute angle suggests functional significance. The authors have postulated that the angle of entry of the common canaliculus into the lacrimal sac may explain the lack of reflux in pathologic conditions associated with an enlarged sac. As the lacrimal sac increases in size, its expansion is limited medially and posteriorly by the bony lacrimal sac fossa. Thus there is more expansion laterally and anteriorly. The lateral expansion may cause kinking of the canaliculus, which functionally blocks the canaliculus–sac junction (Fig. 10-12). External pressure applied to the sac may accentuate the functional valve. In patients with



VIEW IMAGE

FIGURE 10-12 Pattern of angulation within the canalicular system at the canaliculus–lacrimal sac junction: hypothesis for one-way valve phenomenon. **A** and **B**, Looking at the right eye from above (i.e., anterior aspect is at the bottom of the image); the medial aspect (ethmoid sinuses) is at the right side of the image. **A**, Normal lacrimal anatomy. Canaliculi (*c*) bend posteriorly to pass behind the medial canthal tendon, and the common canaliculus (*cc*) bends anteriorly directly behind the medial canthal tendon to enter the lacrimal sac (mean angle of 58° to the lateral wall of the sac). **B**, Kinking and collapse of the common canaliculus at its junction with the lacrimal sac may occur with sac enlargement, leading to a one-way valve effect, preventing reflux of sac contents in certain cases of dacryocystitis, lacrimal sac mucoceles, and acute dacryocystic retention. (Adapted from Tucker NA, Tucker SM, Linberg JV. The anatomy of the common canaliculus. Arch Ophthalmol 1996;114:1231–1234.)

dilated lacrimal sacs not exhibiting a functional valve, the angulation of the common canaliculus, as it enters the sac, may not be acute enough to have a valve effect.[46]

Malik et al.[47] reported radiographic measurements of the lacrimal sac and nasolacrimal duct (Table 10-1). Any distention of the sac greater than 4 mm on the frontal radiograph is considered pathologic. The lacrimal sac ends in a slight taper inferiorly caused by a mucosal fold, the valve of Krause, just above the inferior rim of the orbit. The nasolacrimal duct, which extends 15 to 20 mm in length, begins at this level and may have a small portion of its course within the orbit before entering the bony canal (intraosseous component). This intraorbital segment is approximately 1 cm in length. Within the nasolacrimal duct there is a midsection mucosal constriction, the valve of Taillefer, just superior to the inferior turbinate bone, and a distal constriction, the valve of Hasner. The duct empties through the valve of Hasner into the inferior meatus of the nose, beneath the inferior turbinate. This inferior, or meatal, component usually opens into the nasal cavity 5 mm below the vault of the inferior meatus (anterior aspect) but may extend more inferiorly down the lateral wall of the inferior meatus before entering the nasal cavity. Such inferiorly located valves tend to have a more slit-like opening rather than the fold of mucosa forming Hasner's valve seen in the more superiorly located valves.

In the normal DCG, the canaliculi, lacrimal sac, and nasolacrimal duct are not dilated. On the frontal images, the lacrimal sac and nasolacrimal duct have a linear configuration. The fascia of the orbicularis oculi, which splits to enclose the lacrimal duct and sac, is thick and taut and indents the lumen at the junction of the lacrimal sac and nasolacrimal duct 0.7 cm above the bony canal opening.[9] On the lateral film, the nasolacrimal duct is seen to change direction slightly, inclining posteriorly. This marks the site of the valve of Krause. This combination of indentation and mild kinking caused by the change in nasolacrimal duct system (NLDS) direction may explain why the junction of the lacrimal sac and duct is the most frequent site of obstruction. A second change in direction, more acute, and also posteriorly inclined, is noted at the valve of Taillefer. On a lateral film, the course of the lacrimal sac and nasolacrimal duct should extend along a line from the medial canthus to the first maxillary molar.[42] The lacrimal sac may normally be three times as wide on the lateral image as on the frontal image.[9] Contrast material is identified entering the nasal cavity. In a patent system, the contrast medium will immediately drain from the nose into the pharynx and onto the base of the tongue, with the patient tasting the solution within a few moments. Normally 0.5 to 1.0 ml of contrast medium is injected per side. There should be free flow of contrast through the NLDS into the nasal cavity (inferior meatus). A mild increase in injection pressure may overcome an area of ''relative'' obstruction that may represent secretions or a partial stenosis, which would otherwise have been incorrectly interpreted as obstruction, with implications for treatment decisions. Three anatomic narrowings normally occur and may be noted: at the junction of the common canaliculus and lacrimal sac (valve of Rosenmüller or ''inner punctum''; at the junction of the distal lacrimal sac and nasolacrimal duct (valve of Krause); and at the distal valve of Hasner. These physiologic narrowings must not be mistaken for strictures or obstructions that are also more commonly located at these same sites.

Various mechanisms have been proposed to explain the drainage of tears. These anatomic and physiologic mechanisms, or their dysfunction, are poorly assessed by imaging modalities. Recent interest in the specialized vascular plexus, including cavernous tissue, which closely surrounds the lacrimal sac and nasolacrimal duct and connects caudally with the cavernous body of the nasal inferior turbinate, offers a further theory of tear outflow.[48, 49] Congestion within the vascular plexus affects the tear outflow system, allowing either obstruction or rapid transit of tear fluid. Paulsen et al.[50] propose that the previously described NLDS valves (Rosenmüller, Aubaret, Beraud, Krause, and Taillefer) may be based on different states of swelling of the cavernous body network and should be considered speculative (which may partly explain their inconsistent descriptions in the literature). (In the section Dacryoscintigraphy, see Normal Examination for further discussion of tear outflow.)

Table 10-1
NORMAL LACRIMAL DIMENSIONS

Area	Dimension (mm)	Mean (mm)	Range (mm)
Lacrimal sac	Vertical diameter	11.10	6–14
	Lateral diameter	2.43	1–4
	Anteroposterior diameter	4.00	1–6
Nasolacrimal duct	Vertical diameter	20.97	13–26
	Lateral diameter	2.30	1–4
	Anteroposterior diameter	2.84	1–4

From Malik SRK, Gupta AK, Chaterjee S, et al. Dacryocystography of normal and pathological lacrimal passages. Br J Ophthalmol 1969;53:174–179.

PATHOLOGY OF THE NASOLACRIMAL DRAINAGE SYSTEM

The lacrimal gland situated laterally and superiorly to the globe secretes tears. Under normal circumstances, the tears either evaporate from the surface of the globe or drain into the nasolacrimal passages and pass into the inferior meatus of the nose. Tearing may have several causes.[9] Excessive lacrimation may result in inadequate evaporation or drainage caused by a greater than normal volume of tears. In this situation, the DCG will appear normal. Much more commonly, excessive tearing represents obstructive epiphora, which results from complete or incomplete obstruction or from a functionally inefficient lacrimal system that cannot adequately handle the normal flow of tears. When there is an obstruction or stenosis, the DCG is abnormal. In a symptomatic patient, if contrast medium does not reflux into the superior canaliculus of an otherwise normal NLDS, a repeat study with cannulation of the superior canaliculus should be performed (Fig. 10-8D). There may be an inadequate or altered relationship of the puncta to the ocular surface or an abnormally small punctum inhibiting the transmission of tears into the lacrimal drainage system. In

Copyright © 2003, Mosby, Inc. All rights reserved.

such circumstances, the DCG will be normal. It must be emphasized that the introduction of a cannula into the puncta does not allow radiographic or physiologic assessment of the puncta. Observations regarding laxity of the lower lid, scarring or stenosis of the puncta, or other abnormalities of the lid may be better assessed clinically and should be commented on during the performance of the DCG. Such relationships may require functional assessment, such as with DSG. Permeable (patent) passageways, normal on DCG, may be functionally inefficient and better assessed with DSG. Finally, nasal obstruction may cause epiphora, occluding the valve of Hasner or the adjacent nasolacrimal canal. The venous plexus surrounding the NLDS is in direct communication with the venous plexus of the nasal mucosa. Edema within the nasal mucosa leads to venous plexus engorgement and secondary compression of the nasolacrimal duct.

Obstruction of the nasolacrimal duct system (NLDS) in the great majority of patients is due to idiopathic inflammation and scarring, which causes a spectrum of clinical symptoms ranging from partial occlusion to total obstruction.[51] Clear epiphora, secondary to nasolacrimal duct obstruction, represents a milder presentation. Mucoid epiphora results if bacterial overgrowth occurs in the stagnant fluid of the lacrimal sac. Clinical deterioration will include further signs of dacryocystitis (inflammation of the lacrimal sac) such as a medial canthal mass with increasing tenderness, mucopurulent discharge, secondary conjunctivitis, periorbital cellulitis, and a walled-off abscess in the lacrimal sac. The radiologist investigating the NLDS should be aware of this clinical spectrum and should understand that subtle cases of dacryocystitis require careful physical examination, including lacrimal irrigation.[51]

Dacryocystitis occurs because of obstruction of the flow of tears from the lacrimal sac. The obstructive etiology may be congenital or acquired, including inflammatory, infectious, infiltrative, traumatic, or neoplastic causes. All such processes must be considered as possible underlying factors in the presentation of dacryocystitis. In patients with nasolacrimal duct obstruction, the inflammation and fibrosis may be secondary to coexisting infectious colonization within the lumen of the lacrimal sac. Culture results of conjunctival and nasal specimens have not been predictive of lacrimal sac flora.[52] Assessment of the bacterial flora at the inferior lacrimal sac–nasolacrimal junction, using direct biopsy methods during 132 DCR procedures, to explore the possibility of primary bacteriologic etiology of the inflammatory response, gave positive culture results in 41.7% of the obstructed nasolacrimal duct systems undergoing DCR.[53] Of the isolates cultured, 78.5% were gram-positive bacteria (of this group 76.5% were *Staphylococcus* sp.) and 21.5% were gram-negative bacteria. Nine specimens yielded more than one organism. These organisms were found in patients with and without a history of infection, dacrycystitis, or the presence of a mucocele. Of the isolates, 69.2% were from patients with no history of dacryocystitis or mucocele, suggesting that the infection may have been the primary cause of the nasolacrimal duct obstruction. Conversely, the lack of positive cultures in a significant proportion of the above patients suggests etiologies other than bacterial invasion as the primary cause of obstruction, and organisms isolated may represent resident flora and not be causative.[54] DeAngelis et al.[53] have noted a greatly diminished prevalence of *Streptococcus pneumoniae* over the past 10 years. Others have noted a higher proportion of gram-negative bacteria associated with chronic dacryocystitis.[55]

One should try to distinguish between acute and chronic bacterial dacryocystitis. Acute dacryocystitis manifests as a painful swelling of the lacrimal sac, with surrounding erythema and edema. Pus may be expressible by pressure over a tender lacrimal sac. The bacteria reside in the wall of the sac, and treatment should be via the systemic route.[56] Complications include orbital cellulitis (usually limited to preseptal tissues), corneal involvement, lacrimal sac mucocele, and, rarely, orbital abscesses. The most common organisms implicated are *Staphylococcus aureus* in acquired cases and *S. pneumoniae* in congenital cases, although, due to the large number of potential causative organisms (gram positive or gram negative, aerobic or anaerobic), cultures and smears of expressed punctal secretions are desirable.

Chronic dacryocystitis is characterized by swelling of the lacrimal sac, which may or may not be painful, and with minimal if any surrounding inflammation. The bacteria reside in the lumen of the sac, necessitating treatment by local irrigation as well as by the systemic route.[56] A history of previous attacks of acute dacryocystitis may be present. Patients with chronic dacryocystitis and incomplete obstruction of the nasolacrimal duct may have superimposed bouts of acute dacryocystitis if duct patency is altered by swelling or debris in the duct system. For proper eradication of infection and resolution of dacryocystitis, the lacrimal obstruction must be eliminated to ensure adequate drainage of the nasolacrimal system. Chronic or recurrent dacryocystitis may require DCR. An obstructed lacrimal sac or lacrimal sac distention alone must be differentiated from dacryocystitis and its associated inflammatory changes.

Acute dacryocystitis is commonly associated with preseptal cellulitis. Infection of the lacrimal sac will preferentially localize in the preseptal space since the orbital septum inserts at the posterior lacrimal crest and acts as a significant anatomic barrier to prevent infections extending from the lacrimal sac posteriorly into the orbit. Orbital cellulitis rarely and orbital abscess very rarely result from acute dacryocystitis.[57, 58] The onset of a lacrimal sac abscess must be treated aggressively to prevent possible extension to adjacent tissues as an extraconal or intraconal orbital abscess.[57–60]

In a review of 148 patients with orbital abscesses, acute dacryocystitis was not the source of infection for a single patient.[61] Acute drainage of a lacrimal sac abscess is indicated, especially if it may be the source of orbital infection. In hyperacute dacryocystitis, treatment, although controversial, favors external drainage rather than intranasal (DCR) drainage. A DCR performed following resolution of the acute inflammation reduces the otherwise high risk of late failure due to extensive scarring.[58]

An intraconal abscess in a 1-month-old infant with congenital nasolacrimal duct obstruction (congenital dacryocystitis) suggests that anatomic barriers to infection may be less well defined in neonates than in adults.[62]

Subacute to chronic dacryocystitis may represent later stages of acute dacryocystitis that do not respond sufficiently to antibiotics or that may develop owing to persistent obstruction of the lacrimal system distal to the lacrimal sac.

Copyright © 2003, Mosby, Inc. All rights reserved.

A chronic lacrimal sac abscess (with the lacrimal sac swollen and filled with pus) or low-grade chronic dacryocystitis with intermittent exacerbations may result. Failure of antibiotic treatment of a lacrimal abscess due to chronic or subacute dacryocystitis is associated with obstruction of the lacrimal drainage system distal to the lacrimal sac, preventing drainage of pus from the lacrimal sac. Janssen et al.[60] have presented a subgroup of such patients who may be offered an alternative to DCR such as temporary stent placement within the nasolacrimal duct, along with systemic and topical broad-spectrum antibiotic coverage. This allows drainage of pus from the sac and relief of the infection, with no incidence of exacerbations or extension of the active inflammatory process. Long-term patency of the lacrimal duct system was not ensured by dacryocystoplasty. Surgical DCR was considered if reobstruction of the lacrimal duct system occurred.

Swelling (with or without fluctuance), erythema, and tenderness in the medial canthal area, extending inferior to the medial canthal tendon, simulating acute dacryocystitis or itis.[63, 64] Such cases of pseudodacryocystitis may be distinguished by the lack of a purulent discharge in the tear reflux, lack of a previous history of epiphora, or failure to note tearing between episodes of inflammation. Probing, irrigation, or DCG will confirm patent lacrimal systems. Inflammatory disease within the anterior ethmoid air cells may be noted on CT or MR imaging, with bone dehiscence of the lacrimal sac fossa better identified on CT. Such inner canthal fistulae associated with ethmoiditis are rare and tend to develop above the level of the medial palpebral ligament,[65] in contrast to acute dacryocystitis or lacrimal sac abscess, which extend inferior to the medial canthal tendon. An ethmoidectomy procedure rather than DCR is the treatment of choice for patients with primary sinonasal disease.

Obstruction

Obstruction may be due to various causes, including congenital stenosis, inflammatory diseases, calculi, trauma including foreign bodies, and tumors. Filling defects may be associated with an inflammatory process (see the section on Chronic Canaliculitis). DCG can assess both complete and incomplete obstructions (Figs. 10-5 to 10-8). The most common site of obstruction is the neck of the lacrimal sac, at its junction with the nasolacrimal duct, and it is usually due to inflammation (chronic dacryocystitis) and scarring of the nasolacrimal duct. Marked dilatation of the sac is usually clinically noted inferior to the level of the medial canthal tendon. Dilatation of the canaliculi is often associated with a dilated sac. Obstructions of the sac may be associated with a membrane at the medial end of the common canaliculus. Such a membrane must be identified and removed for a dacryocystorhinostomy (DCR) to be successful.[66] With pure sac obstructions, DCR should be successful in 100% of the cases, without the need for temporary intubation. Of the failed DCRs, 12% to 40% were due to common canaliculus problems.[66, 67] Thus high-quality images, especially of the canaliculi, are necessary to predict which patients will do poorly with simple DCR. The size of the lacrimal sac mucosal flap needed for the DCR may also be predicted from the DCG.

DCG may also define a cicatrized lacrimal sac, seen in chronic dacryocystitis. A cicatrized sac is more difficult to operate on, and is associated with poorer results than normal or enlarged lacrimal sacs when treated by endoscopic intranasal DCR in either primary treatment or revision patient populations. In these patients, the DCG can suggest that an external DCR should be the treatment procedure of choice.[37]

The next most frequent site of obstruction is the common canaliculus.[9, 16, 47] Common canalicular obstructions are most frequently related to chronic dacryocystitis or a ball valve effect of dacryoliths.[68] Accurate localization of canalicular obstruction has treatment implications (Fig. 10-8). Two thirds of common canalicular obstructions occur at the medial end, at the junction with the lacrimal sac, where a thin membrane, as a complication of inflammation within the sac, is present.[69] The common canaliculus appears as a well-defined structure on DCG. Treatment includes excision of the membrane and a DCR with temporary intubation (3 months) of the canaliculus. One third of common canalicular obstructions occur at its lateral end, as a result of mucosal obstruction where the superior and inferior canaliculi join. The entire common canaliculus is dissected out before mobilizing the lacrimal sac or periosteum. The scarred (stenosed) segment of canaliculus is excised, and the canaliculi are reanastomosed into the lateral wall of the lacrimal sac as a canaliculo-DCR. Occlusions or stenosis of the inferior or superior canaliculus may be due to traumatic laceration, canaliculitis, canalicular papillomas, and chronic pilocarpine or phospholine iodide use, and can be treated with DCR and temporary or permanent canalicular tubes or canaliculo-DCR reconstructive surgery.[68] Preoperative DCG diagnosis, with the exact location and length of occlusions/stenoses, therefore aids surgical planning and treatment decisions.

Less frequently, obstructions occur within the superior aspect of the lacrimal sac. Noncongenital obstructions of the distal nasolacrimal duct tend to be incomplete and are more frequently associated with adjacent sinus disease, inflammatory or neoplastic, than with intrinsic pathology of the nasolacrimal duct.[9] Neoplasms of the nasolacrimal duct (or sac) are rare, usually arise from pseudostratified columnar epithelium, and cause duct obstruction (Fig. 10-13A-C). On DCG, irregular duct obstruction, although nonspecific, should suggest or include this diagnostic possibility.[70]

Radiographically, the lacrimal sac above the obstruction will usually be dilated and have an ovoid or rounded configuration rather than a normal linear shape. The dilated sac or ‘‘mucocele of the lacrimal sac’’ is palpable below the medial canthus.[9] Occasionally the lacrimal sac will be constricted above the obstruction because of a cicatricial inflammatory response or fibrosis.[71]

Reflux of contrast medium into the conjunctival sac through the uncannulated punctum will occur when obstruction is present. This occurs early during the injection of a small volume of contrast medium. When the obstruction is incomplete, the DCG usually demonstrates dilation of the lacrimal sac above the incomplete obstruction. Contrast material must be visualized entering the nasal cavity to confirm the incomplete nature of the obstruction. Dilated

FIGURE 10-13 CT-DCG of mass lesions: inner canthus. CT-DCG allows better assessment of the extent of adjacent tissue involvement than DCG alone and better assessment of NLDS involvement than CT alone. **A** to **C**, Patient presents with left inner canthus prominence and epiphora. **A**, DCG shows superior displacement of the left canaliculi (*arrow*) with no visualization of the left lacrimal sac or nasolacrimal duct. **B**, Coronal CT-DCG shows displacement of the proximal NLDS (*solid arrow*) by a soft-tissue mass in the inner canthus (*open arrow*).

Illustration continued on following page

lacrimal sacs, distorted by fibrosis, must be differentiated from distended cystic diverticula or true cysts of the lacrimal sac (Fig. 10-14). Traumatic dislocation of the lacrimal sac must also be considered.

Obstructions in the lower part of the nasolacrimal duct occur less frequently. The diameter of the bony canal is one of the contributing factors for occurrence of strictures at this site. Women are affected much more frequently than men (up to 80%), probably related to their narrower bony canal.

Fistulae

Congenital lacrimal sac fistulae are relatively uncommon, estimated to occur in 1 per 2000 births.[72] Fistulae may also be postinflammatory (chronic dacryocystitis), posttraumatic, or postsurgical.[42, 72, 73] The fistula most commonly originates from the lacrimal sac (lacrimal sac-cutaneous fistula) but may arise from the canaliculi or nasolacrimal duct. Most of the fistulae are unilateral and located inferonasal to the medial canthus. Patients may be asymptomatic and overlooked for some time after birth or may demonstrate tearing from the fistula. the eye, or both.[74] Fistulae are usually associated with long-standing obstruction of the nasolacrimal drainage system (Fig. 10-15). A previous DCR may have been performed without recognition of the fistula's presence. The majority of patients present with epiphora, which may be delayed in onset; occasionally an inflammatory lesion of the lower lid may be the presenting sign.

Congenital lacrimal fistulae probably result from failure of involution of the lacrimal anlage, the thickened surface ectoderm of the nasooptic fissure, which becomes buried in the mesenchyme between the nasal and maxillary processes to form the nasolacrimal drainage system. Instead, this anlage proliferates, canalizes, and forms a fistula, whose cutaneous opening is just medial and inferior to the medial canthus.[27] The fistulous tract may also be incomplete and end blindly in the subcutaneous tissues near the lacrimal sac.[75] Welham and Bergin[76] have proposed that a congenital fistula may be caused by aberrant budding of the canaliculi, with the fistula representing a supernumerary or aberrant canaliculus. Absence of a superior or inferior canaliculus or absence of a punctum has been noted to be associated with lacrimal fistulae.[76, 77] The epithelial lining of the fistula is identical to that of a normal canaliculi.[75] A hereditary or familial pattern of presentation of lacrimal fistulae has also been noted.[27]

If the fistula is not clearly demonstrated by the DCG, placement of a lacrimal probe into the external opening, in conjunction with the DCG, may help show its origin from the nasolacrimal drainage system. Recommended treatment includes DCR, common canalicular dissection, fistula excision, and temporary canalicular intubation to bypass the distal obstruction and prevent common canalicular obstruction and recurrence of the fistula.[76] Others recommend excision alone or with nasolacrimal intubation, without DCR if there is no evidence of nasolacrimal obstruction.[74] Patients with very minor or no symptoms may simply be kept under observation.

Diverticula

Diverticula represent outpouchings of a lacrimal drainage pathway and are usually the result of a long-standing obstruction (Fig. 10-7F,G). They are most commonly asymptomatic, small, and clinically undetected. Occasionally they may be associated with episodic or permanent symptoms of nasolacrimal duct obstruction (chronic tearing discharge) and may present as a mass lesion without associated nasolacrimal duct obstruction.[78] Less often, they may present as an acute infection, either diverticulitis or

Copyright © 2003, Mosby, Inc. All rights reserved.

dacryocystitis secondary to duct obstruction. Congenital lacrimal sac diverticula most frequently result from the spontaneous rupture (outpouching) of the lacrimal sac wall in acute dacryocystitis associated with congenital nasolacrimal duct obstruction.[79]

Acquired lacrimal sac diverticula most commonly result from a weakening of the lacrimal sac wall after inflammation or trauma, including probing or irrigation, or after incision and drainage procedures for dacryocystitis.[78]

Diverticula of the lacrimal sac may be associated with dacryoliths, which may intermittently obstruct the opening of the lacrimal sac and increase the pressure of fluid within the sac, with resultant weakening of the lacrimal sac wall and diverticular formation in an asymptomatic patient.

Epiphora, associated with these diverticula, may result from mechanical pressure on the lacrimal drainage system rather than a primary intraluminal blockage of a duct or sac. Slow evolution of a lacrimal sac diverticulum is typical.[80] The most common location is at the junction between the lacrimal sac and the nasolacrimal duct. The communication between the diverticulum and the lacrimal sac may be clearly open or may be valvular and limited, limiting diverticular drainage. The relative rarity of reports of lacrimal diverticula in the literature more likely reflects their

frequently asymptomatic nature and difficulty in demonstrating them routinely by DCG. In many cases, only the obstruction or impression on the lacrimal sac due to the mechanical pressure of the diverticulum is noted. Only DCG or ultrasonography may reveal the narrow communication, while CT/MR imaging may better display the size, extent, and cyst-like characteristics of the diverticula, and their relationship to the nasolacrimal drainage system, for those lesions unable to be directly visualized by DCG.[78, 80]

Diverticula of the canaliculi, lacrimal sac, or nasolacrimal duct are usually the result of a long-standing obstruction (Fig. 10-7F,G), and the diverticula will remain until adequate drainage of the obstructed or partially obstructed nasolacrimal system is restored. It is not possible to diagnose diverticula preoperatively without a DCG. Clinically, distended cystic diverticula may resemble a dilated lacrimal sac or a true cyst of the lacrimal sac, which does not communicate with the NLDS.

Lacrimal Sac Cysts

Cysts arising from the lacrimal sac epithelium are rare. Although these cysts may be congenital, inflammatory, or traumatic in origin, most think they arise from diverticula of the lacrimal sac, with the cyst forming when the communication to the lacrimal sac closes off.[81] The cyst may communicate directly with the sac or may be anatomically separate. Lacrimal sac cysts usually present as a nonreducible, well-defined, slow-growing, painless mass in the inner canthus, below the level the medial canthal tendon.[82] Epiphora, which may be secondary to pressure on the sac, is a common symptom, and/or the cyst may be associated with a patent nasolacrimal drainage system.[81] Pressure over the mass will not alter the size of a lacrimal sac cyst but may reduce the size of a diverticulum. The pathologic description of a cystic cavity lined by columnar to cuboidal epithelium may not help differentiate a lacrimal sac cyst from a diverticulum or mucocele of lacrimal sac etiology. Treatment consists of total excision of the cyst. If there is any communication with the lacrimal sac, lacrimal sac wall repair and simultaneous DCR is indicated.

Lacrimal Calculi

Lacrimal sac dacryoliths may be present in 10% to 30% of patients presenting with chronic dacryocystitis.[83–85] In addition to tearing, patients with lacrimal sac calculi may present with a history of mucopurulent discharge, lacrimal sac distention, tenderness in the medial canthal region, and recurrent dacryocystitis. The frequency of partial nasolacrimal duct obstruction with dacryocystitis has been reported in as many as 65% to 70% of patients.[83, 84, 86, 87] Primary and

secondary dye tests indicate partial obstruction of the nasolacrimal duct (Figs. 10-7, 10-16C,D, 10-17D,E, and 10-18A-C).[85]

Wilkins and Pressly[86] stressed the intermittent but chronic nature of tearing unresponsive to treatment in patients with lacrimal calculi. There may be a history of repeated, painful lacrimal probings, occasionally with transient relief caused by either repositioning or fragmentation of the stone. The extreme inconsistency of nasolacrimal irrigation in patients with lacrimal calculi is most impressive, and by itself may suggest the diagnosis. Such variability of results may occur within a short period (minutes), with one irrigation showing reflux and suggesting obstruction and a second irrigation showing normal flow into the nasal cavity. Friable or fragmented calculi within the sac are subject to the currents produced by an irrigation, and cranial movement of the calculus will allow free flow, while caudal movement of the lacrimal sac calculus creates a ball-valve effect and complete nasolacrimal occlusion.[86] Weber et al.[88] have noted that dacryoliths do not change in size or shape, representing permanent filling defects in the DCG. Dacryoliths should be differentiated from retained thick secretions or air bubbles. Air bubbles injected into the nasolacrimal system represent an artifact that can simulate a concretion, although bubbles tend to be rounder and more sharply defined. A cross-table lateral view will demonstrate the air bubble floating in the lacrimal sac, while concretions tend to settle in the more dependent inferior posterior aspect of the sac and do not change location with altered positions of the head as quickly as air bubbles (Figs. 10-7M,N and

Illustration continued on following page

10-19A). Lacrimal sac calculi are often unsuspected at the time of surgery even though they are a common cause of epiphora. Preoperatively, such a diagnosis should be more strongly suspected in the younger patient (under age 50 years) with no obvious cause of epiphora.[86] In Jones'[84] and Wilkins and Pressly's series,[86] 65% and 53% of patients, respectively, under age 50 with epiphora of unknown etiology had calculi detected during DCR. Several reports have noted dacryoliths to be more common in younger and female patients. Reports indicate that 58% to 80% of patients with dacryoliths are under 50 years of age.[83, 84, 86, 87] Between 68% and 95% of patients with dacryoliths are female.[83, 84, 86, 87]

Most reports indicate that the frequency of lacrimal sac stones between 6% and 18% in patients undergoing dacryocystorhinostomy (DCR) for nasolacrimal duct obstruction. Yazici et al.'s[89] of 163 DCR cases noted a difference in the frequency of lacrimal sac dacryoliths in patients subcategorized as to etiology of obstruction. They report that 9.2% of the cases with primary acquired (idiopathic) nasolacrimal duct obstruction (PANDO) had dacryoliths. However, no dacryoliths were noted in a smaller group (38 cases) with a known cause of obstruction (congenital, traumatic, sinonasal surgery), a finding also noted in other series.[83, 84, 86] In analyzing the symptoms of patients with PANDO and dacryoliths compared to those without dacryoliths, Yazici et al.[89] noted the increased likelihood of acute medial canthal swelling (lacrimal sac distention or acute dacryocystic retention) without infection in patients with dacryoliths. They emphasized the distinction between lacrimal sac distention (no erythema or extreme tenderness, with a mucoid but not a purulent discharge) and dacryocystitis. Forty-two percent of the 12 patients with dacryoliths had simple acute lacrimal sac distention versus 5% of the 103 patients without dacryoliths. The previously reported greater frequency of acute dacryocystitis with dacryoliths may not have considered the distinction between lacrimal sac distention (retention) and acute dacryocystitis.

In these patients[89] with PANDO requiring DCR, the presence of lacrimal sac distention and male gender were more frequently associated with dacryoliths. There was no statistical significance related to age. Partial nasolacrimal duct obstruction and a history of cigarette smoking were relative risk factors for stone formation. Other studies[83, 84, 86] have noted a higher incidence of calculi in younger patients (under age 50) and in females.

The calculi may be fragmented, especially if the lacrimal drainage system has been probed. At surgery (DCR) the lacrimal sac must be carefully assessed and the puncta irrigated to ensure that all fragments are removed. Although the etiology of lacrimal calculi is obscure, predisposing factors such as stasis and infection are frequently associated

with calculus formation. An obstruction allowing partial drainage may facilitate the accumulation of debris. The etiology of dacryoliths, however, is more complex, with dacryolith formation noted in patients with no narrowing or compromise of the drainage system. The dacryolith is typically friable, often molding itself to the sac and duct. This friability helps explain the spontaneous passage of large dacryoliths through obstructed or anatomically narrowed ducts.[90, 91] The calculus consists of lamellae of cellular breakdown products and mucoproteins with or without calcium or ammonium salts.[89] Eyelashes, and occasionally particles of makeup, may be found in dacryoliths and may have acted as a nidus for dacryolith formation.[92–94] Herzig and Hurwitz,[95] in a series of 246

Persistent increased activity in the left lacrimal sac (*open arrow*), superior canaliculus, and inferior canaliculus (*solid arrows*) caused by obstruction to outflow in the left lacrimal sac. Dacryolith in the left lacrimal sac. (See Fig. 10-18A-C for DCG and CT of the same patient.)

patients treated surgically, of whom 14 had calculi, were unable to demonstrate any systemic electrolyte abnormality predisposing to stone formation. They noted no abnormality of tear or serum calcium, phosphorus and uric acid concentrations, tear to serum calcium ratios or calcium-phosphate products. Accumulation (supersaturation) of electrolytes in an obstructed tear sac eventually leads to precipitation of a stone. Such precipitation can occur when obstruction is sudden (as in trauma or nasal surgery) or when obstruction is long-standing and associated with infection. The great majority of stones consist of calcium phosphate.[95]

The presence of a dacryolith, with persistent clinical features not responding to conservative treatment and requiring a DCR, may make endoscopic DCR more difficult or necessitate a larger opening for lacrimal sac exploration. An external approach may be necessary.[96]

Fungi have been noted in canalicular concretions but less frequently in lacrimal sac concretions. Anaerobic infection (*Actinomyces israelii*) is more common in canalicular stones (Fig. 10-7K,L), whereas *Candida*, an aerobic fungus, has been noted in lacrimal sac concretions.[97, 98] The relatively large size of fungi probably acts as the nidus, which, in a setting of chronic stasis, promotes or initiates calculus formation. The stasis, in a significant number of patients, is midlevel in the sac and probably results from the nature of the split fascia of the orbicularis muscle at this level, causing chronic dacryocystitis. The occurrence of lacrimal calculi is generally more frequent in female patients, but in at least one series male predominance was noted.[89] There have been variable results in identifying bacteria or fungi in association with lacrimal sac calculi. Jones[84] did not find any infectious agents in his results, while Berlin et al.[83] found bacteria or fungi rather commonly in lacrimal sac stones. They used routine hematoxylin-eosin stains as well as special fungal stains and recommended cultures for aerobes, anaerobes, and fungi. They noted DCG filling defects within the lacrimal sac in 4 of 11 patients found to have dacryoliths of the lacrimal sac at DCR.

Cast-like fungus obstruction of the nasolacrimal duct is uncommon.[98] When fungi occlude the lacrimal drainage

system, it is usually by formation of a stone or cast. *Aspergillus fumigatus* is an extremely rare cause of canalicular or lacrimal sac obstruction. *Aspergillus* produces hyphae, forming a ball or plug that obstructs the lacrimal system by mechanical obstruction without invading the surrounding tissues. Many cases have concomitant keratoconjunctivitis.[99] A lacrimal sac *Aspergillus* plug, presenting with initial intermittent obstruction and progressing to total obstruction, with discharge from the lacrimal punctum and extreme discomfort, may show no involvement of adjacent tissues (CT, operative and pathologic assessment), with CT only displaying an enlarged lacrimal sac. The discomfort is presumed to be caused by the stretched lacrimal sac capsule.[99] In patients with mechanical obstruction (i.e., plug) as an etiologic consideration, the planned DCR may be initiated with lacrimal sac exploration prior to osteotomy of the lacrimal fossa. The DCR may be abandonned if unnecessary.[99]

Calculi related to the canaliculi are discussed in the next section.

Since stasis secondary to an anatomic obstruction is likely to be the precipitating factor,[95] massaging, probing, or irrigation techniques to flush out the dacryoliths are restricted to incomplete obstructions and are limited in success due to the persistent stenosis of the nasolacrimal duct system (NLDS) or the increased size of the prestenotic dacryolith. Surgical removal of the dacryolith, in conjunction with an external DCR, is the standard treatment. The presence of calculi in the NLDS represents a limitation for endonasal DCR treatment. There have been attempts at nonsurgical management of dacryolithiasis using stent placement to correct an obstruction at the lacrimal sac–nasolacrimal junction. After fragmentation of the stones during stent implantation, the fragments passed through the stent with saline irrigation.[100]

In cases of dacryolithiasis associated with incomplete

(eight patients) or complete (two patients) obstructions, Wilhelm et al.[101] have performed balloon dilatation of the NLDS, principally to widen the stenosed obstructing segment, so that the dacryoliths may pass more easily into the nasal cavity during forced irrigation with saline. If stone passage was not achieved because of persistent stenosis or large dacryolith size, further balloon dilatation (eight patients) was used to crush the calculi. Incomplete washout of calculi by forced irrigation was supplemented by retrograde passage of a 6.3F sheath across the stenosis. With the tip inferior to the dacryolith, repeat forced irrigation is performed, with active aspiration of the fragments through the sheath. In two patients, additional fragmentation of the dacryolith with a gooseneck Amplatz snare, passed retrograde through the sheath, was followed by successful irrigation combined with aspiration. Attempts at stone removal may be unsuccessful when bending of the sheath occurs or if fragments are too large to pass through the sheath.[101] For those patients with preintervention complete obstruction, stent implantation was initially necessary to restore drainage function. Stone removal itself, by such nonsurgical techniques, should not be considered without concomitant treatment of the stenosis or obstruction.[100, 101] (See the section on Dacryocystoplasty and Stent Placement for a more detailed procedural discussion.)

Chronic Canaliculitis

Chronic infective canaliculitis, although relatively uncommon, is significant because of its specific radiologic and clinical features (Fig. 10-8). In 1854, von Graefe[102] was the first to attribute this condition to an infectious source. Although chronic canaliculitis was called *streptothrix*, since the anaerobic bacterium *A. israelii* was the most frequent causative agent. Numerous other anaerobic agents have been identified, including *Nocardia* and *Fusobacterium* species, *Arachnia propionica*, and *Bacteroides*, as well as aerobic fungi, including *Candida*, *Aspergillus*, and *Blastomyces*,[83, 103] emphasizing the need for both anaerobic and aerobic cultures. Secondary bacterial infections should be treated independently.

Chronic canaliculitis, as with most lacrimal drainage afflictions, affects women more often than men and the lower canaliculus more than the upper.[103] Involvement of more than one canaliculus rarely occurs,[104] and the disease

VIEW IMAGE

is almost always unilateral.[83, 103] Clinically, the affected lid is swollen from the lacrimal punctum to the medial canthus, with a chronic mucopurulent discharge or particulate matter expressed (with difficulty) from a pointing dilated punctum. Erythema and induration over the canaliculus may be noted. Demonstration of concretions within the canaliculus virtually establishes the diagnosis, although concretions can also form around small foreign bodies or hair (eyelash) in the canaliculi.[94, 103] Organisms such as *Actinomyces* or, less frequency, *S. aureus*, form filamentous aggregates (sulfur granules), which distend the canaliculus and impede the drainage of tears. However, the canaliculus is often patent to syringing, obscuring the correct diagnosis.[85] Adequate treatment requires complete removal of concretions, material that has accumulated within the canaliculus. Expression and curettage may be adequate, but often incision and debridement of the affected canaliculus is necessary. Antibiotics used without surgical correction are unsuccessful. Such patients therefore usually present with an extensive list of previously prescribed medications. Chronic unilateral conjunctivitis should always suggest the possibility of canaliculitis.

DCG shows dilation and irregularity of the affected canaliculi, with an appearance of sacculation, beading, or diverticula. Such dilation is nonspecific and may be noted proximal to any obstructive or stenosing lesion. Dilation without stenosis or the presence of irregular filling defects (due to concretions) within the canaliculi is more specific for a chronic infectious etiology such as actinomycosis. Filling defects in the absence of concretions or sulfur granules may represent actinomycotic filaments. The degree of dilation is related to the presence of filling defects and is unrelated to the infective organism.[103] Classically, the distal nasolacrimal system fills and is normal, with no evidence of inflammatory change despite the severity of the proximal canalicular duct involvement. The extent of involvement is characteristically limited to the proximal canaliculi such that the common canaliculus and lacrimal sac are usually normal (e.g., the common canaliculus was normal in 15 of 18 patients in one series).[103]

Concretions (dacryoliths) are more frequent in the lacrimal sac. Such concretions are less consistently associated with chronic infection than are concretions in the canaliculi.[83, 86] Chronic viral canaliculitis (e.g., ocular vaccinia, herpes zoster, or simplex ophthalmicus, viral conjunctivitis) tends to cause scarring, with stenosis or occlusion of the puncta and/or canaliculi, and therefore differs from the classic description of chronic infective canaliculitis.[105] Obstruction of the medial half of both canaliculi is often herpetic or trachomatous in origin.[106] In contrast to conjunctival infections caused by microbes, certain viral infections extend deeper into the stratified squamous epithelium of the canaliculi to involve the elastic layer, with resultant scarring and stenosis.[105]

Posttreatment Considerations

Postsurgical Considerations

Radiopaque tubes between the nasal cavity and medial canthus may be used in conjunction with DCR (canaliculo-DCR) to maintain patency within the canaliculi (Figs. 10-7I-J, 10-9, 10-20). Surgical clips may occasionally be present in the region of the medial canthus, and their relationship to the nasolacrimal drainage system may be important in cases of postsurgical obstruction. The relationship of the nasolacrimal sac to the DCR osteotomy site is assessed by CT. DCR is a relatively successful surgical procedure in 85% to 90% of cases, with an average failure rate of approximately 10%.[30, 107–110] DCR failure may be

Copyright © 2003, Mosby, Inc. All rights reserved.

due to delayed obstruction at the surgical anastomosis by granulation tissue, fibrosis, or osteogenic activity or by secondary stenosis of the canaliculi. The failed DCR patient will have recurrence of epiphora and frequently recurrent dacryocystitis. DCG shows DCR failure to be related to problems distal to the common canaliculus in 60% of cases.[66] A residual inferior portion of the sac, with its bony covering (incomplete osteotomy), may produce inadequate drainage requiring a direct surgical approach on the anastomosis. This is in contrast to a canaliculo-DCR, which is required in 12% to 40% of failed DCRs where the obstruction is in the common canaliculus.[66, 67] It may not be possible on DCG to differentiate an obstruction of the common canaliculus from a closed osteotomy site in patients with a previous DCR.[107] Scarring of the ostium (rhinostomy site) and errors in ostium location are the major causes of surgical failure.[111, 112] Adhesions to the nasal septum (synechia) from the rhinotomy site may case obstruction and DCR failure. These adhesions are detectable on CT.[111] On DCG, lacrimal sac diverticula, directed medially toward the midline, may suggest adhesions between the ostium and the nasal septum.[111]

The relatively increasing percentage of patients with postsurgical canalicular problems may reflect increasing attention to the lacrimal flap/osteotomy site and/or reflect the iatrogenic effects of dilations and probings of the canaliculi preoperatively or during surgery.

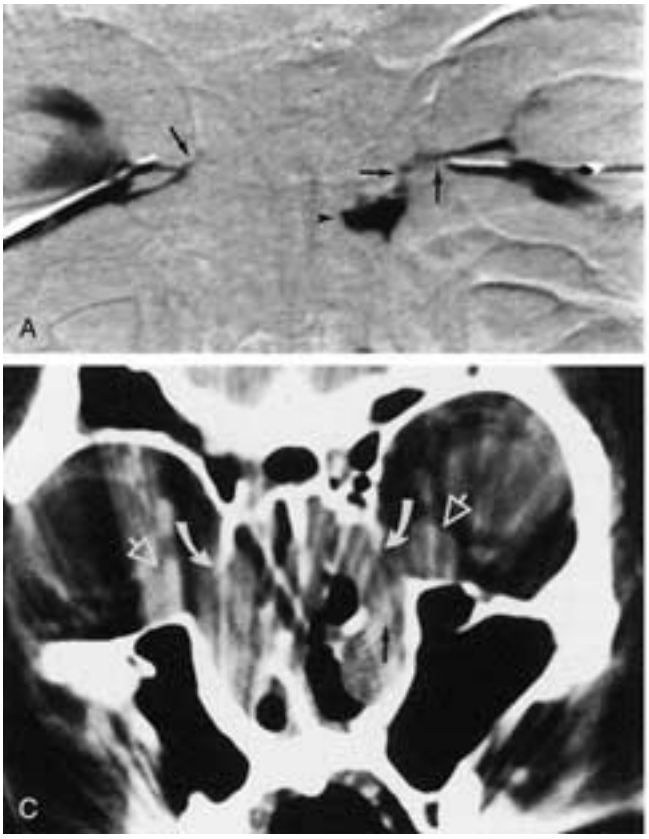
Hurwitz et al.[113] studied the effects of surgery and/or radiation treatment for paranasal sinus tumors on the NLDS of 19 patients. Of those patients treated surgically, the majority (75%) did not develop obstruction even though the NLDS was anatomically altered, with the nasolacrimal duct frequently being shortened and the lacrimal sac displaced (Fig. 10-10). During maxillary sinus surgery, the lacrimal bone and nasolacrimal canal are frequently removed, and these patients tended to have obstruction in the lower part of the NLDS and were amenable to treatment by DCR. Stenosis or irregularity of the lacrimal sac or one of the canaliculi may develop secondary to scar tissue formation but does not tend to cause obstruction.

Postirradiation Considerations

Patients treated with postoperative radiotherapy tended to have more profound abnormalities of the lacrimal system than those treated by surgery alone, with the delicate structure of the canaliculi most susceptible to irradiation injury and subsequent obstruction.[105, 106, 113] Such patients may need to be treated by prolonged intubation of the canaliculi (silicone tubing) or (canaliculodacryocystorhinostomy), with a success rate of only 60% to 70% versus 80% to 95% for uncomplicated lower NLDS obstruction.[114] Doucet and Hurwitz[114] postulated whether or not prophylactic placement of intubation tubes (silicone or glass stents) at the time of surgery would be beneficial for patients undergoing postoperative radiation therapy to prevent the canalicular stenosis or obstruction.

Postchemotherapy Considerations

The onset of epiphora, due to the development of punctal and canalicular fibrosis, soon after the weekly administration of docetaxel, an effective first- or second-line antineoplastic agent for the treatment of breast or prostate cancer,



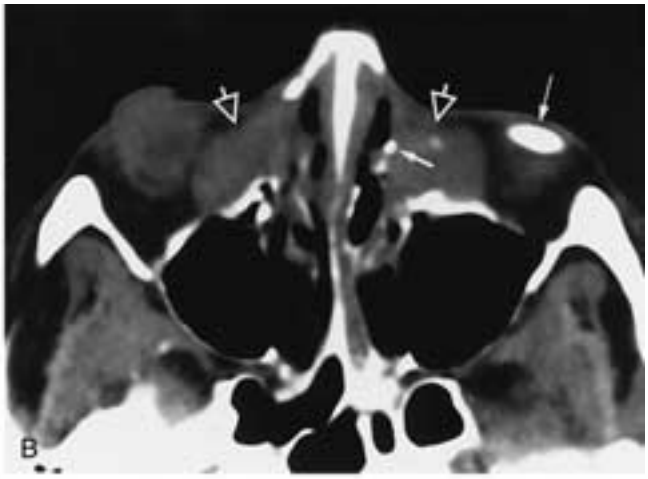


FIGURE 10-20 Bilateral inner canthal masses: previous bilateral DCG recurrent right epiphora. **A**, DCG. Right superior canalicular injection shows severe stenosis of the common canaliculus (*oblique arrow*), reflux into the inferior canaliculus, and no filling of the lacrimal sac. Left inferior canaliculus shows stenosis medially (*vertical arrow*) and a fibrosed lacrimal sac (*horizontal arrow*), with contrast entering the nasal cavity through the previous DCR (*arrowhead*) at the inferior aspect of the lacrimal sac. **B**, Axial CT-DCG shows bilateral inner canthus soft-tissue masses (*open arrow*). Contrast material is seen in the left NLDS (*solid arrow*) and conjunctival sac (*thin arrow*). **C**, Coronal CT-DCG (artifact from dental restorations). Inner canthus masses (*open arrows*) appear to be contiguous with soft-tissue densities of the nasal cavity through previous DCR osteotomy sites (*curved arrows*) and the left nasolacrimal canal (*black arrow*).

VIEW IMAGE

has recently been described in three patients.[115] The pattern of fibrosis involved all four puncta and canaliculi. Discontinuation of the agent led to resolution of symptoms in only one of the three patients (who may have had less advanced fibrosis). The mechanism of canalicular stenosis may be secondary to secretion of the chemotherapeutic agent in the tear film, with fibrosis resulting from the direct contact (local) of the agent in the canaliculi. Alternatively, the mucous membrane lining the puncta and canaliculi may undergo fibrosis secondary to systemic effects of the drug, similar to the widespread edema and fibrosis noted elsewhere within the body.

Canalicular stenosis had previously been described in association with other chemotherapeutic agents, such as 5-fluorouracil.[116, 117] Screening for epiphora and canalicular stenosis has been advocated for this patient population, with early treatment consideration of silicone intubation or punctoplasty, while the patient is receiving the chemotherapeutic agent, to prevent complete closure of the canaliculi and the need for conjunctivo-DCR and Jones tube placement.

DACRYOSCINTIGRAPHY

In 1972, Rossomondo et al.[118] introduced a radionuclide technique to assess the lacrimal passages (Figs. 10-16, 10-21, and 10-22). This technique offers a more physiologic, less expensive, more sensitive, and more comfortable modality for assessing epiphora.[119–122] The ease of performance and the noninvasive nature of the procedure tend to encourage routine bilateral studies. DSG can also provide a quantitative dynamic analysis of tear drainage physiology. DCG, although the most commonly used imaging technique for evaluating the anatomy and pathology of the lacrimal drainage system, does not provide physiologic information.[113, 123] Because the pressure required to inject the DCG contrast material overcomes any functional occlusion of the NLDS, a normal DCG in a patient with epiphora offers no information related to functional stenosis or obstruction.

Technique

The patient is placed in a modified sitting position so that the head rests on a modified slit-lamp support that includes a chin rest, forehead support, and straps to immobilize the head for the study. Just before the instillation of radionuclide, manual pressure over the inner canthus empties the lacrimal sacs. With the head tilted back, a drop (approximately a 10 µl aliquot) of the solution technetium 99m pertechnetate or 99m-Tc-sulfur colloid is placed in the lateral conjunctival sac using an automatic micropipette. Instillation of larger volumes will simply overfill the conjunctival sac, resulting in spillage onto the face.[124] The patient's head is then placed within the supporting frame, and a micropinhole (1 mm) collimator is placed just anterior (e.g., 8 to 9 cm) to the nasion and between the two orbits in the upper central field of the gamma camera. Dynamic acquisition of scintigraphic images starts immediately after instillation of the radiopharmaceutical. Patients are instructed to blink every 5 seconds during data

Copyright © 2003, Mosby, Inc. All rights reserved.

acquisition. A computer is set up for a two-phase dynamic acquisition with the following protocol: phase 1 (stimulated phase, 0 to 2 minutes), 5 second scans for 24 frames; phase 2 (initial drainage phase, 2 to 12 minutes), 10 to 15 second scans for 40 frames. A variation of this technique has the patient remain still but blink normally, with the dynamic acquisition of tracer distribution imaged every 10 seconds for the first 160 seconds.[22] Static views are then taken routinely at 5, 10, 15, and 20 minutes.

An alternative technique includes an 8 µl drop of 99m-technetium-tin colloid, containing no more than 4 MBq and capturing 48 consecutive 15 second images, using a 2 mm pinhole collimator placed 2 cm from the eye, centered on the medial canthus.[26] Using this technique, each eye is imaged separately. The 2 mm aperture offers a preferred balance between resolution and increased sensitivity (sampling of radiation emitted). Other authors favor a 3 mm aperture or vary the distances (e.g., 1 cm subject to collimator, 5 cm nasion to collimator, or 8 cm subject distance).[125–127]

The passage of radioactivity is followed on a video display unit. An area of interest (e.g., interpalpebral fissure and canaliculi) can be outlined on a rapid-sequence video display terminal and quantitative data analysis achieved by the computer interfaced to the gamma camera (Fig. 10-22).

Radiopharmaceutical activity enters the canaliculi rapidly and then progresses along the NLDS, with activity increasing in the lacrimal sac and decreasing in the canaliculi. Data analysis and time activity curves for the radiopharmaceutical to leave an area of interest (various constructed points along the NLDS) can be obtained. The $T_{1/2}$ (the time required for one half of the radioactive dose to disappear) for a specific site can be estimated by finding the slope of the curve plotting the natural logarithm of counts per second from the region of interest against time.[128] The examination is terminated when the radiopharmaceutical reaches the nasal cavity. Residual radioactivity is flushed out by a saline eye bath at the end of the study (Fig. 10-16D). The radiation dose to the lens (4 to 21 mrad) is minimal, 1% of that from a DCG[129] or less than 2% of the radiation from an anterioposterior skull film (i.e., 4 vs. 200 to 370 mrad).[118, 130] The usual aliquot administered contains between 50 and 100 µCi of 99m-Tc.[118] The radiation dose will be increased if the lacrimal drainage system is blocked. If lacrimal fluid turnover is minimal and disappearance occurs only by physical decay, the maximum absorbed dose to the nearpoint of the lens will be 400 mrad.[129]

Normal Examination

Both lid margins are visualized, and the canaliculi are seen after approximately 10 seconds. The radiopharmaceu-

($T_{1/2}$ is beyond the limits of the scan time.)

tical can be seen progressively in the lacrimal sac and nasolacrimal duct, terminating in the nasal cavity. The valve of Hasner is usually seen as a reduction of scintillations at the lower end of the tracer column. A significant proportion of normal volunteers showed delayed passage of the radiopharmaceutical between the lacrimal sac and the nasal cavity, such that dacryoscintigraphy (DSG) is deemed unreliable for assessing the nasolacrimal duct, that is, the drainage system inferior to the lacrimal sac.[20, 125, 127] The flow of tears (radiopharmaceutical) from the conjunctival cul-de-sac to the lacrimal sac occurs in approximately 12 seconds, yet the radiopharmaceutical may not reach the nasal cavity for 10 to 20 minutes.[125] The elimination of tears is affected by the blink-driven ''lacrimal pump,''

Copyright © 2003, Mosby, Inc. All rights reserved.

which depends on the muscular blinking action of the eyelids, that is, the superficial and deep insertions of the preseptal and pretarsal orbicularis oculi of the lower and upper eyelids.[131] This component of the orbicularis envelops the lacrimal system, thus transmitting pressure through the tear outflow tract. With the eyelids closed, the ampulla and canaliculi are shifted medially, shortened, and compressed, and the tear fluid is driven into the lacrimal sac, which has a negative pressure. When the eyelids are open, pressure in the ampulla decreases and the pressure in the lacrimal sac increases, expelling fluid out through the nasolacrimal duct.[132]

The lacrimal pump can exert a suction effect at the punctum on the lacrimal secretions during blinking (Fig. 10-23)[124, 133, 134] Transit times of radioisotope to the lacrimal sac may be greatly prolonged in patients who do not blink but rather keep their eyelids closed. Occasional exceptions occur in patients with orbicularis contractions during lid closure. The elderly, with open lacrimal passages but inefficient tear fluid transportation, may also show delayed transit.[135] The greatest decay of tracer from the conjunctival sac occurs within the first few blinks.[136, 137] The relative drainage to the inferior and superior canaliculi remains controversial. Several studies concluded that activity was greater in the inferior than the superior canaliculus.[26, 128, 138] White et al.[126] showed that the superior and inferior canaliculi are of equal importance in lacrimal drainage and that no statistical difference exists between the amounts of tears that drain into either canaliculus. Similarly, Daubert et al.[139] showed no significant difference in tear flow between the upper and lower canaliculi in normal, patent, asymptomatic systems. If one canaliculus was blocked in an anatomically healthy NLDS, a compensatory increase in tear flow might occur in the other canaliculus such that no significant difference (statistical analysis $p < 0.05$) in time activity would be noted for $T_{1/2}$ of the interpalpebral fissure radioactivity (overall tear flow).[139] A single (upper or lower) canaliculus is sufficient for basal tear drainage but will not be sufficient to drain reflex tear secretion in 50% of cases.[140] The lacrimal drainage system is a closed system with a negative pressure, and occlusion of one canaliculus increases the suction effect and the subsequent increased tear flow through the patent canaliculus.[139]

The drainage of tears involves a number of different mechanisms including capillary action,[131, 133, 134] aided by contraction of the lacrimal part of the orbicularis oculi with blinking,[131, 141, 142] and craniocaudad distention of the sac with passive wringing of the sac because of its medial attachment and helically arranged fibrillar structure.[49] A vascular plexus, comparable to a cavernous body and embedded in the wall of the lacrimal sac and nasolacrimal duct, contains specialized blood vessels including regulatory arteries, a dense network of capillaries, capacitance veins, and cushion veins, which can reduce or interrupt venous blood outflow to allow large amounts of blood to accumulate inside the capacitance veins.[50] This cavernous body, which connects to that of the inferior turbinate of the nasal cavity, may facilitate closure and opening of the lumen of the nasolacrimal duct system (NLDS) by swelling and shrinkage of the cavernous body, with consecutive regulation of the tear outflow. When the net outflow of blood from the cavernous body is less than its inflow, there is mucosal expansion, functionally decreasing tear outflow. This represents a protective mechanism against foreign bodies or toxic stimuli that enter the conjunctival sac. In addition to increased lacrimal gland tear production, the decreased tear outflow, by the cavernous body response allows the increased tear pool to flush out the conjunctival sac while protecting the NLDS. The pathophysiology of functional lacrimal drainage insufficiency (epiphora despite a patent

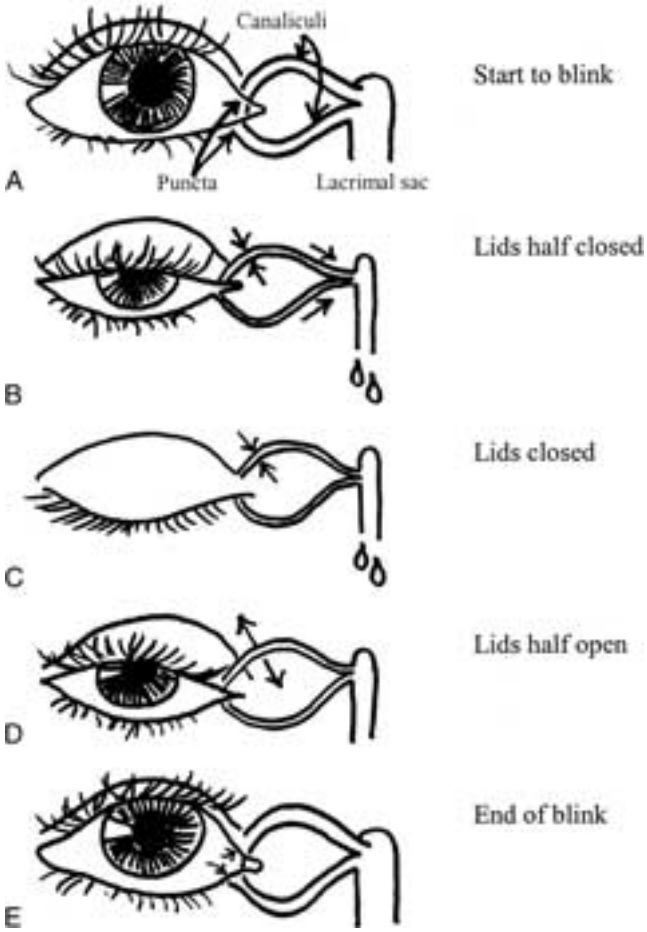

FIGURE 10-23 Lacrimal pump theory of Doane. **A**, Start of blink. The canaliculi and sac contain tear fluid from the previous blink. **B**, Lids half closed. As the upper lid descends, papillae containing punctal openings elevate from the medial lid margin, forcefully meeting the opposing lid margin, occluding the puncta, and preventing fluid regurgitation. Further lid closure squeezes the canaliculi and sac (through the action of the orbicularis oculi), forcing the contained tear fluid into the nasolacrimal duct. **C**, Lids closed. Maximum compression of the canaliculi and sac, with all fluid expressed into the nasal cavity. **D**, Lids half open. Puncta still occluded by opposing medial lid margins. Release of pressure by the orbicularis oculi with cessation of compression action. Elastic walls of the passages try to expand to their normal shape, with a resultant partial vacuum and negative pressure and with a suction effect forming within the canaliculi and sac. **E**, End of blink. As lid separation progresses, suction force holding the punctal region together is released and the punctal papillae ''pop'' apart, with negative intraluminal pressure drawing tear lake fluid into the canaliculi and sac. (Redrawn adaptation from Doane MG. Blinking and the mechanics of the lacrimal drainage system. Ophthalmology 1981;88:844–851 and adaptation of the above by Dale DL. Embryology, anatomy, and physiology of the lacrimal drainage system. In: Stephensen CM, ed. Ophthalmic, Plastic, Reconstructive, and Orbital Surgery. Boston: Butterworth-Heineman, 1997;19–30.)

NLDS during syringing) may be explained by the presence of the cavernous body.[50] Malfunctions within the vascular bed may lead to disturbances in the tear outflow cycle, ocular congestion, or total occlusion of the NLDS and may be caused more acutely by allergic conjunctivitis, rhinitis, or hay fever, or more chronically, as with stenoses after dacryocystitis or dacryolithiasis.[50] Persistent epiphora after dacryocystorhinostomy (DCR) may be due to destruction of the surrounding cavernous body. The cavernous body may also play a role in the absorption of tear fluid by the NLDS epithelial lining mucosa and alternative draining by the surrounding venous plexus before reaching the nasal cavity.[48]

Complete Obstruction

Total obstruction, if present, is identified on DSG (Fig. 10-16). Even though the lacrimal sac may be filled with lacrimal secretions, debris, or even concretions, there is physiologic reflux of the secretions into the conjunctival sac.[143, 144] Therefore, fresh secretions or radiopharmaceutical from the DSG will enter the lacrimal sac. The study is sensitive to the site of obstruction so that the appropriateness of surgery, such as DCR, or placement of drainage tubes can be determined. The smaller pinhole aperture helps improve resolution that may still be suboptimal in differentiating canalicular from proximal lacrimal sac pathology. However, DCG will provide anatomic information to complement DSG when necessary. If a DSG shows obstruction proximal to the lacrimal sac, the common canaliculus or the inferior and superior canaliculi or puncta may be obstructed.

Incomplete Obstruction: Functional Nasolacrimal Duct Obstruction

Patients with epiphora who have a normal DCG or a normal clinical lacrimal irrigation test usually have physiologic obstruction to the drainage of tears. FNDLO has been interpreted to mean symptomatic epiphora, with a lacrimal system patent to syringing and no detectable cause of epiphora external to the lacrimal drainage system (no cause for increased lacrimation and no lid abnormality present).[22] The main level of functional blockage (lacrimal drainage delay) in the lacrimal system was easier to detect objectively with DSG than with DCG. When discrepancies in the identified level of functional block occurred (41% of combined DSG-DCG studies of FNLDO patients), Wearne et al.[22] noted that the DSG detected an obstruction at a more proximal level in 16 of 20 patients. DSG/DCG discrepancies were most likely due to the pressure injection of DCG contrast dilating lesser degrees of more proximal stenosis. Positive scintigrams were subdivided into those demonstrating prelacrimal sac delay (13%), delay at the lacrimal sac–nasolacrimal duct junction (35%), or delay within the nasolacrimal duct (42%). Prelacrimal sac delay was defined as holdup at the inner canthus or failure of the tracer to reach the lacrimal sac by the end of the dynamic phase (160 seconds). Delay at the lacrimal sac–nasolacrimal duct junction (35%) was defined as preductal delay with early filling of the lacrimal sac but no sign of sac emptying on the static image at 5 minutes. Delay within the nasolacrimal duct (42%) was defined as intraductal delay with tracer noted in the upper part of the nasolacrimal duct at 5 minutes but no further drainage over the next 15 minutes. Of note, 72% of patients in the above series had clinically bilateral FNLDO.[22] The transit time through the distal part of the nasolacrimal duct and into the nasal cavity, known to show marked variability in normal individuals, was not calculated in their study. It is interesting to speculate whether the marked variability in transit time of normal individuals and patients with FNLDO may be related to functionality of the surrounding vascular plexus (cavernous body) or to variability of resorption of the tear fluid by the NLDS mucosa, as outlined by Paulsen et al.[50] (In the section Dacryoscintigraphy, see Normal Examination for further discussion.) Simultaneous bilateral DSG studies can compare and evaluate the delay in transit of the radiopharmaceutical on the involved side. Frequently, however, the clinically normal side will also reveal abnormal flow. Amanat et al.[20] noted in their patients with a clinically unilateral abnormality that 42% had an abnormal flow pattern by DSG on the contralateral side. Thus the contralateral side was clinically silent relative to the increased symptoms on the primary symptomatic side.

Sensitivity of Dacryoscintigraphy

DSG is more sensitive for detecting obstruction than macro-DCG.[127] Normal DSG was always associated with duct patency on DCG, allowing a protocol specifying that DSG should be the first investigation; if it is normal, DCG is unnecessary. In Rose and Clayton's series,[127] 26% of the NLDS showing obstruction on DSG had a normal DCG. In a series[22] limited to patients with a clinical diagnosis of FNLDO, both DSG and DCG were very sensitive in detecting abnormalities (95% and 93%, respectively), with DCG including the performance of a delayed upright 5 minute film and DSG results including quantitative analysis.[121] Hanna et al.,[26] in comparing syringing to DSG in patients with epiphora, found that 65% of apparently patent systems on syringing demonstrated abnormalities on DSG. Abnormalities included 40% with decreased entry into the NLDS or canalicular obstruction on DSG. In those patients with abnormal syringing, the most common site of obstruction on DSG was at the lacrimal sac outflow. In these patients, canalicular obstruction was seen with almost the same frequency as in those with patent syringing (35% vs. 33%).[26] Both DCG and syringing require cannulation. Either lid puncta and proximal canalicular functional or anatomic abnormalities may be missed on the basis of the cannulation or the pressure of the injection or irrigation.

In syringing, false negatives or false positives may result partly from the subjective nature of the patient's ability to interpret or be aware of saline entering the nasopharynx. In the Hanna et al. series, 18% of those who had a positive syringing test had a negative DSG.[26]

Weber et al.[88] found the greatest application for DSG to include children; puncta unable to be cannulated after surgery; posttrauma; and functional obstructions, especially if the DCG was normal.

COMPUTED TOMOGRAPHY

DCG cannot display information beyond that of the drainage lumen proper. Although displacement of the NLDS may be shown by DCG, the peripheral extent of mucosal or periductal disease cannot be defined. In these cases, CT may be indicated either initially or as a complementary study. The understanding that epiphora (or dacryostenosis) results from a multitude of etiologies should suggest a more selective imaging approach for each patient. When appropriate imaging studies are performed, diagnostic accuracy in dacryostenosis may be significantly improved, ensuring that diagnosis is not delayed and that the appropriate operation is done or that surgery can be avoided if contraindicated.[63, 145] Classifications of acquired lacrimal drainage obstruction further emphasize the need to understand the etiology of dacryostenosis.[145–148] Appropriate decisions are based on whether or not signs or symptoms result from processes arising outside the NLDS or whether abnormalities outside the NLDS are present that could adversely affect the outcome of the proposed lacrimal surgery. If such factors cannot be determined through clinical means, imaging tests should be performed that will limit surprises at the time of surgery.[149] Specific patients with epiphora and all patients presenting with an inferomedial orbital mass lesion are candidates for CT. The broader base of anatomic and pathophysiologic relationships to adjacent tissues offered by CT becomes helpful in making treatment decisions. As noted by others,[145, 150] dacryostenosis may be much more closely related to local nasal or sinus problems than has been previously emphasized. Similarly, the etiology of FNDLO and its relation to sinonasal disease has been largely unappreciated. High-resolution, thin-section CT imaging (1.0 to 2.5 mm slice thickness) may be an appropriate and useful modality for assessing the NLDS, its immediate bony confines, the lacrimal fossa, the adjacent orbit, the facial skeleton, paranasal sinuses (especially the agger nasi and ethmoid bulla air cells), and the nasal cavity. The increasing capabilities of volume acquisition thin-slice CT, with multiplanar and 3D reconstruction availability and shorter time acquisition, offer excellent imaging resolution and patient compliance. Anatomic depiction of the nasolacrimal sac and duct is well seen in the axial plane. Coronal assessment may be helpful, especially to display the junction of the lacrimal sac and duct and the relationship of the medial orbital floor or nasal cavity structures to the NLDS. Intravenous enhancement is routinely used (except in the trauma patient), since one is frequently assessing the possibility or the extent of an inflammatory or neoplastic lesion. The radiation dose absorbed by the lens during spiral CT for assessment of the NLDS has been measured at 1.8 to 2.6 mSv[151] compared to 0.68 mSv for DS-DCG.[18]

Radiographic Anatomy

Plain or intravenous enhanced CT (Fig. 10-24) does not identify the superior and inferior canaliculi or the common canaliculus. The canaliculi may be visualized by placement of topical contrast medium into the conjunctival sac (see the section on Combined CT-Dacryocystography).

The normal lacrimal sac and duct may be either tear-filled (soft-tissue density) or air-filled (Fig. 10-25). The lacrimal sac will normally not exceed a 2 mm diameter unless distended with air.[152] The sac itself is a membranous structure, noted within the bony lacrimal fossa.

The frontal process of the maxillary bone and the lacrimal bone form the lacrimal sac fossa. The fossa is a clearly demarcated depression bound anteriorly by the anterior lacrimal crest, contiguous with the inferior orbital rim, and posteriorly by the posterior lacrimal crest, a linear elevation along the anterior aspect of the lacrimal bone. The frontal process of the maxillary bone and the lacrimal bone contribute varying proportions to the formation of the lacrimal sac fossa. The anteroposterior position of the vertical suture between these components is variable. The lacrimal bone separates the upper half of the lacrimal fossa from anterior ethmoid air cells and the inferior part from the middle meatus of the nasal cavity. Closely surrounding the lacrimal sac is a rich venous plexus separating the sac from the adjacent lacrimal fascia, an anterior extension of the orbital periosteum, which splits at the posterior lacrimal crest to invest the lacrimal sac.

Enhancement of the venous plexus or the closely associated superficial and deep heads of the orbicularis oculi may help identify the lacrimal sac within the soft-tissue density of the medial canthal structures if the lacrimal sac is not air-filled. Horner's muscle represents the lacrimal component of the superficial and deep heads of the orbicularis oculi muscle attaching to the anterior and posterior lacrimal crests, respectively. These fibers act as a muscle envelope, surrounding the lacrimal fascia and sac. They are not distinguishable on CT from the anteriorly placed medial palpebral ligament, the subjacent lacrimal fascia, or the posteriorly positioned orbital septum.[42, 153]

The medial canthal ligament attaches to the anterior lacrimal crest and forms an anterior margin to the lacrimal sac. The medial orbital septum attaches just posterior to the posterior lacrimal crest. The lacrimal fossa and sac are therefore preseptal structures. Below the level of the medial palpebral ligament, the lacrimal sac is not enveloped by the orbicularis oculi muscle and therefore is potentially weaker at this site, offering less resistance to intraorbital spread of infection[153] or possibly to perforation by antegrade manipulation of instruments within the nasolacrimal drainage.[154]

In DCR, the opening in the bony wall between the lacrimal sac and the nasal cavity is initiated with perforation of the thin lacrimal bone at the inferior portion of the lacrimal sac fossa. In external DCR, a large bony opening measuring 1.5 cm is produced through the nasal wall of the lacrimal fossa, including the anterior lacrimal crest (thicker frontal process of the maxillary bone).[30] In endonasal DCR, the bony opening, at the same site, tends to be smaller and does not include the anterior lacrimal crest.[33] Because of the increasing popularity and frequency of use of endonasal DCR, using various laser and endoscopic techniques (and to a lesser extent endocanalicular laser DCR techniques), attention to the anatomic structures that need to be penetrated by the procedures has grown. Lacrimal bone thickness and variations in sinonasal configuration that may limit access or the feasibility of specific surgical approaches (endonasal or endocanalicular) have clinical treatment implications.[155, 156] The ability of various lasers to penetrate

bone is less than that of the traditional mechanical instruments, especially when the fiberoptic laser is used through the endocanalicular route.[155]

Hartikainen et al.[155] noted the mean thickness of the lacrimal bone at the lacrimal fossa to be 106 µm, with 67% of patients having a mean thickness of less than 100 µm. Only 4% of patients had a mean thickness greater than 300 µm. A slightly decreased thickness of bone with increasing age was not significant. The lacrimal bone, although variable, tends to be thin, about 0.1 mm on average, and so can be easily penetrated with most surgical instruments. The osteotomy is then enlarged to include the thicker bone (frontal process of the maxilla) to the appropriate size required by the DCR technique.[155] Of 48 lacrimal patients with fossa dissections, only 1 displayed a significant anatomic variant, with no real lacrimal fossa bilaterally. The lacrimal sac was bounded, nasally and inferiorly, entirely by the frontal process of the maxillary bone, and the vertical suture was situated temporal to the tiny posterior lacrimal crest. Such a variation makes endoscopic or endocanalicular DCR techniques difficult or impossible.[155]

Yung and Logan,[156] in a smaller cadaveric series, reported an average thickness of 57 µm in nine dissections, excluding one abnormally thick lacrimal bone (296 µm). In all cases, the part of the lacrimal passage covered by the thin lacrimal bone corresponded to the upper part of the nasolacrimal duct and the lower part of the lacrimal sac. The thin lacrimal bone covered the posteromedial part of the upper nasolacrimal duct, with the thicker frontal process of the maxilla still covering the main part of the nasolacrimal duct. The authors note that the lacrimal bone is always situated immediately anterior to the mid-third of the uncinate process, an anatomic landmark in endonasal DCR procedures. An extremely large anterior ethmoidal air cell, the agar nasi, can be juxtaposed completely between the nasal cavity and the entire lacrimal fossa, leading to considerable confusion during DCR.[157]

A light source positioned within the lacrimal sac will transmit through the tiny lacrimal bone but not the thicker maxillary bone. Such transillumination can assist placement of the DCR osteotomy during endonasal DCR. Therefore, any surgical process (e.g., laser beam) directed at the area of maximum illumination (from the light source) tends to only remove the bone at the posteromedial portion of the inferior lacrimal sac–superior nasolacrimal duct rather than its entire width, with a resultant small lacrimal window.[156]

The lacrimal sac tapers inferiorly and is continuous with the nasolacrimal duct. The fascia investing the lacrimal sac also continues inferiorly to invest the nasolacrimal duct and become continuous with the periosteum surrounding the inferior meatus. The entire lacrimal drainage system remains continuous with the preseptal space even though the nasolacrimal duct is directed posteriorly and inferiorly.

The valve-like folds of mucosa (valves of Krause) separating the lacrimal sac from the nasolacrimal duct are not recognized on CT. An encircling bony canal along the medial aspect of the maxilla identifies the intraosseous component of the duct. The duct itself is usually collapsed and occupies only a small portion of the cross-sectional diameter of the bony canal. The most inferior portion of the nasolacrimal duct, approximately 5 mm in length, represents the membranous (or meatal) portion of the canal, passing beneath the nasal mucosa before emptying into the inferior meatus through a slit-like or funnel-shaped opening, the valve of Hasner.

The nasolacrimal canal represents the bony canal, which encloses and protects the nasolacrimal duct, connecting the inferior aspect of the lacrimal sac fossa to the inferior meatus of the nose. The maxilla contributes the greatest component, with the formation of a longitudinal groove, the lacrimal sulcus. The gap between the lips of this groove is completed by the articulation of two other component bones, the descending process of the lacrimal bone from above and the lacrimal process of the inferior nasal concha from below.[158] The form, dimension, and direction of the bony lacrimal

passages show considerable variation, mainly due to the extent to which the individual bones participate in their formation, with the lacrimal bone being the most variable.[158]

The bony nasolacrimal canal has been reported to be a structure highly variable in size, with differences associated with age, sex, and race. There has been recent interest in CT imaging of the bony nasolacrimal canal to assess normal CT values and to establish values that may be causative or a component of factors leading to nasolacrimal duct obstruction. Assessment of an epiphora patient population with PANDO may indicate minimal bone canal diameter acceptable for balloon dacryocystoplasty (DCP) versus DCR.[159–161] PANDO is an idiopathic process, whereas secondary obstructions are attributed to a recognized causative factor.[146, 161] See Table 10-2. The prevalence of PANDO in women has generated interest in possible etiologies. Proposed mechanisms include heightened levels of inflammation in women, leading to tissue swelling and obstruction; hormonal imbalances causing transient changes in the mucous membranes; and anatomic differences between men and women.[146, 150, 161] A narrower bone environment, combined with inflamed mucosal tissues, would place the raw mucosal surfaces in close proximity, enhancing the chance that the mucosal walls will stick together, forming an obstruction secondary to scar tissue.[160] Generalized deepithelialization of mucous membranes occurs during the menstrual cycle, with smaller nasolacrimal passages being more easily obstructed with epithelial debris. Osteoporotic changes may also be a factor in the female predilection for PANDO. Chronic allergy or maxillary sinusitis may percolate through the porotic bony wall of the sinus and nasolacrimal duct, causing inflammatory changes in the canal and duct, leading to blockage.[162]

Groessl et al.[160] noted that women have significantly smaller anteroposterior dimensions in the inferior nasolacrimal fossa and the midnasolacrimal canal. Janssen et al.,[159] using 2 mm axial CT images photographed on bone windows to measure the minimal transverse diameter of the bony nasolacrimal canal, studied a control group of 50 men and 50 women, as well as a patient group with epiphora and PANDO treated by balloon DCP. The longer anteroposterior diameter of the canal (ranging in size from an average normal of 2.84 mm[47] to an upper limit of 8 mm[158]) was felt to be less useful due to the oblique posteroinferior orientation (15° to 25°) of the nasolacrimal canal relative to the axial image.[159] The smallest diameter of the bony canal appears to be the most relevant measure for ascertaining the origin of an obstruction of the lacrimal drainage system.[159] This smallest diameter is generally found midway along the canal.[160] The mean minimum transverse diameters of the bony canal in the control groups were 3.7 mm and 3.35 mm for men and women, respectively.[159] These measurements are considerably smaller than previously measured transverse diameters of 4 to 6 mm[158, 163] but correlate with the 3 mm diameter[157] or 2.3 mm[47] measurements of other studies, with variations reflecting the different measuring techniques or modalities used. The mean minimal diameter in the epiphora patient group was 3.0 mm, considerably smaller than that of the control groups, suggesting a relationship between a narrower bony canal and obstruction of the NLDS. The broad range of diameters found in the control group (1.5 to 6.3 mm) showed complete overlap with the range found in the symptomatic group (2.0 to 4.2 mm), suggesting that a relatively small minimal diameter of the bony canal is not the sole etiologic factor in PANDO.[159] Further research is needed to ascertain whether a minimum threshold value of the diameter of the bony canal can be determined, below which balloon DCP as a treatment for lacrimal obstruction is contraindicated, making surgical DCR the preferred treatment.[159]

While the majority of patients with clinically suspected PANDO will have histopathologic findings of inflammation and fibrosis, there is a low incidence of significant other pathology of the lacrimal sac, such as neoplasm. These cases can only be identified by biopsy of the lacrimal sac during DCR.[150, 161, 164] Malignant tumors, especially epitheliomas and lymphomas, may first appear as simple dacryocystitis for prolonged periods.[165] Defining the true incidence of unsuspected lacrimal sac neoplasms presenting clinically as PANDO has specific implications in determining whether routine biopsy during DCR is warranted. This would also determine if there is a significant risk of missing an underlying lacrimal sac tumor in patients not undergoing surgical intervention but having procedures such as DCP, or in those undergoing laser DCR, where direct visualization and biopsy of the lacrimal sac are not possible.[164]

When an asymptomatic, exceptionally enlarged nasolacrimal canal is observed, concern for the presence of a relatively uncommon lacrimal sac tumor is raised, since these tumors may grow down into and expand the nasolacrimal canal. Associated CT signs of lacrimal sac tumors should be sought, including a soft-tissue mass of the lacrimal sac, bone erosion, and extension of the mass into adjacent tissues.

There may be variable amounts of air or soft tissue within the confines of the nasolacrimal canal, with air occasionally extending from the inferior meatus to the lacrimal sac. In a large population of patients scanned for other reasons, soft-tissue opacification restricted to the nasolacrimal canal is routinely noted and is considered a normal variant. In 200 nasolacrimal ducts studied by coronal CT, 72% were opaque.[166] Of those ducts associated with normal paranasal

Copyright © 2003, Mosby, Inc. All rights reserved.

sinuses, 79% had an opacified nasolacrimal duct. However, in the lacrimal patient, soft-tissue opacity of the nasolacrimal duct may have more significance and reflect pathologic characteristics of the nasolacrimal duct itself, such as PANDO, or adjacent inflammatory or neoplastic processes extending to the nasolacrimal canal from the lacrimal sac, orbital origins, or sinonasal origins.[145] One should assess the tissues adjacent to the nasolacrimal canal and examine for prominence or abnormal thickness of the lacrimal sac wall. While the lacrimal patient may display soft-tissue opacification of the nasolacrimal canal more frequently on the side of epiphora,[145] the exact significance if this finding is unclear. With such opacification as the only CT finding, the need for further imaging investigations, such as DCG or CT-DCG, must be based on clinical correlation. Obstruction of the nasolacrimal duct with dilatation of the lacrimal sac (lacrimal sac mucocele, dacryocele, dacryocystocele) may cause pressure erosion and enlargement of the nasolacrimal canal, depending on the degree of lacrimal sac enlargement and the level of distal obstruction within the canal. The pressure within the obstructed NLDS results from obstruction at both the proximal and distal aspects and tends to be most profound in congenital dacryocystocele (nasolacrimal mucocele). In congenital dacryocystocele the distal obstruction tends to be at the valve of Hasner, with the classic triad of cystic dilatation of the lacrimal sac, a dilated nasolacrimal duct/canal, and an intranasal cystic mass from the inferior imperforate membrane ballooning into the nasal cavity. In two patients presenting with an intermittent obstruction, Rheeman and Meyer[167] hypothesized that the intraluminal pressure, great enough to cause pressure erosion and dilation of the bone canal, may also reach a level high enough to overcome the obstruction intermittently. Significant nasolacrimal canal enlargement may occur as an incidental normal variant, without evidence of erosion, displacement, or mass lesions. Such findings in asymptomatic patients usually warrant no further investigation. A DCR may help exclude any small neoplastic lesion of the lacrimal sac and nasolacrimal duct. A follow-up CT scan to show lack of change may be justified. Biopsy of the lacrimal sac or duct is not warranted in the absence of any clinical or radiologic evidence of tumor.[167]

Coronal CT (direct or reformatted) may better display the longitudinal course of the nasolacrimal canal but will not directly assess the membranous nasolacrimal duct (compare this to MR imaging of the nasolacrimal canal [Fig. 10-26] or CT-DCG [Figs. 10-19 to 10-27]).

CT Pathology

Dacryocystitis (inflammation and dilation of the lacrimal sac) is usually diagnosable clinically unless associated preseptal or periorbital cellulitis limits an adequate clinical assessment. Enhanced imaging studies are most useful and help differentiate preseptal inflammatory lesions from more specific acute and/or chronic dacryocystitis. CT demonstrates an enlarged lacrimal sac centered around the lacrimal fossa (Figs. 10-17 and 10-28 to 10-30). Axial CT (and/or MR imaging) also distinguishes the postseptal inflammatory lesions (periorbital or orbital abscess), which require urgent surgical intervention, from acute dacryocystitis, a preseptal inflammatory process that is treated nonsurgically (Fig. 10-29). Extrinsic compression or infiltration by an adjacent inflammatory, neoplastic, or traumatic process of the nasolacrimal duct or sac may result in obstruction, enlargement, or dilation of the lacrimal sac and must be considered in the differential diagnosis of medial canthal mass lesions. Mass lesions in the region of the medial canthus and lacrimal sac may represent lacrimal sac diverticula. While these lesions are most commonly small and asymptomatic, they may present as cystic mass lesions, with or without mechanical obstruction of the NLDS. DCG or ultrasound infrequently demonstrates the communication between the lacrimal sac lumen and the diverticulum, such that only indirect signs of compression, displacement, or obstruction are visualized on the DCG. The most common location of these diverticula is at the junction of the lacrimal sac and the nasolacrimal duct. Those larger clinically apparent cystic diverticula tend to appear tense and fluctuant, affixed to the deep tissues but not to the skin.[78] They are almost always located lateral to the lacrimal sac, frequently coursing along the inferior orbital rim deep to the medial aspect of the lower eyelid.[78] With gentle pressure, some may be decompressed through the punctum or into the nose if the communication between the diverticulum and the lacrimal system is patent. Air may be trapped in a diverticulum, enabling a pneumatocele to develop.

Pneumatocele should always be considered in this location, especially with a well-circumscribed roundish or cystic-appearing mass that may contain air or have an air-fluid level. There are usually no associated inflammatory changes and no evidence of lacrimal drainage system obstruction. In contrast to chronic dacryocystitis, which demonstrates a thick-walled lacrimal sac, diverticula tend to be surrounded by an extremely thin fibrous or epithelial/fibrous layer that may not be apparent on CT.[80] These masses do not enhance and suggest a cystic lesion rather than a neoplastic process. Lacrimal sac mucoceles and true lacrimal sac cysts may be difficult to differentiate by imaging. The tendency of lacrimal sac diverticula to extend more laterally at the inferior sac–duct junction, with thinner capsule, may help differentiate these lesions from the lacrimal sac mucocele that tends to expand more superiorly and to have a thicker, enhancing wall and an obstructed nasolacrimal system clinically. Topical administration of contrast medium (DCG-CT) may help define the lacrimal system's patency, as well as the possibility of contrast extending into the diverticulum. However, the communication between the lacrimal system and the diverticulum may be progressively sealed by chronic inflammation, forming an independent cyst (lined by lacrimal epithelium) containing increased caseous or proteinaceous content, and with inflammatory changes thickening its capsule, obscuring its more cystic nature and resembling a more solid mass. MR imaging may better demonstrate the cystic nature of the lesion in such a circumstance.

Lacrimal sac diverticula may be treated by ligation and excision. Those lesions (congenital or postinflammatory) located at the inferior lacrimal sac or nasolacrimal duct and causing obstruction are better treated by DCR.

Lesions arising within the orbit, paranasal sinuses, or nasal cavity may mimic lesions of the nasolacrimal drainage apparatus and present clinically with the same symptomatol-

FIGURE 10-26 Nasolacrimal canal assessed by MR imaging. **A**, Patient with chronic inflammatory disease of the NLDS. Axial T1-weighted postgadolinium image shows mucosal enhancement of the nasolacrimal duct epithelium (*white arrows*). Nasal polypoid tissue is anterior to the nasolacrimal duct (*open arrow*). **B** and **C**, Another patient. **B**, Axial proton density image at the level of the inferior meatus shows the left nasolacrimal duct (*thin arrow*) just proximal to the valve of Hasner. Air in the right nasolacrimal canal is seen as signal void (*curved arrow*). **C**, Axial T2-weighted image scan shows the left nasolacrimal duct (*straight arrow*) within the canal. Air in the right nasolacrimal canal is seen as signal void (*curved arrow*). (See also Fig. 10-25.)

ogy as mass lesions of the inner canthus or inferomedial orbit (Fig. 10-30).[145, 152, 153]

A wide variety of neoplasms (benign and malignant) of the adjacent nasal cavity, maxillary, ethmoid, or even frontal sinuses may manifest as medial canthal masses. (See Table 10-3.) Squamous cell carcinoma and, less commonly, adenocarcinoma represent a majority of the malignant lesions. Inverted papilloma may arise within the lacrimal sac, although more commonly such tumors arise within the adjacent nasal cavity and paranasal sinuses and directly invade the lacrimal sac or spread from the nasal cavity up the nasolacrimal duct to reach the lacrimal sac and inner canthus.

Mucoceles arising in the anterior ethmoid air cells have an intimate relationship with the lacrimal fossa. CT may show opacified expanded anterior ethmoid air cells with thinning and remodeling of bone. Any bone destruction caused by pressure erosion, if present, will be more extensive than that seen with lacrimal sac dilations and will be eccentric relative to the nasolacrimal fossa. In these cases, the lamina papyracea bows toward the orbit.

Dermoids are well-defined lesions of the orbit that result from sequestration of ectodermal elements trapped along lines of embryonic fusion. Such masses tend to localize adjacent to suture lines. Although they are located most frequently adjacent to the frontozygomatic suture, a medial (nasal) extraconal location is also common. The presence of fat density, a fat-fluid level, or rim calcification may help suggest this diagnosis and differentiate a dermoid from a dilated lacrimal sac. Medial orbital or nasal dermoids also tend to be more superomedial. Unlike dacryocystitis or mucoceles of the nasolacrimal sac, such lesions do not

extend into the nasolacrimal duct. Coronal CT may be diagnostic by displaying continuity between the lacrimal sac and the nasolacrimal duct. Encephaloceles or meningoceles may present in the inner canthus as well-defined masses. Their extension superiorly within the nasoorbital tissues should suggest this diagnosis, and a defect in the skull base should be carefully sought. Hemangioma, lymphangioma, and neurofibroma are frequent benign tumors of the orbit. They may be associated with a mass effect and pressure erosion, but they do not cause bone invasion. Occasionally, an isolated varix of the angular vein may manifest as a medial canthal mass or may simulate a lacrimal sac mass. The patient usually presents with intermittent swelling. Tearing may be present if there is compression of the lacrimal drainage system. Regression of the mass with gentle pressure, or an alteration in the size of the mass with Valsalva maneuvers, or with alteration in head position, should suggest this diagnosis.[168, 169]

Malignant lesions arising within the orbit that may present as inner canthal masses include lymphoma, rhabdomyosarcoma, and metastases. Preseptal malignancies, including basal cell and squamous cell carcinomas of the skin and non-Hodgkin's lymphoma, commonly invade the medial canthal tissues. Rarely, plasmacytomas

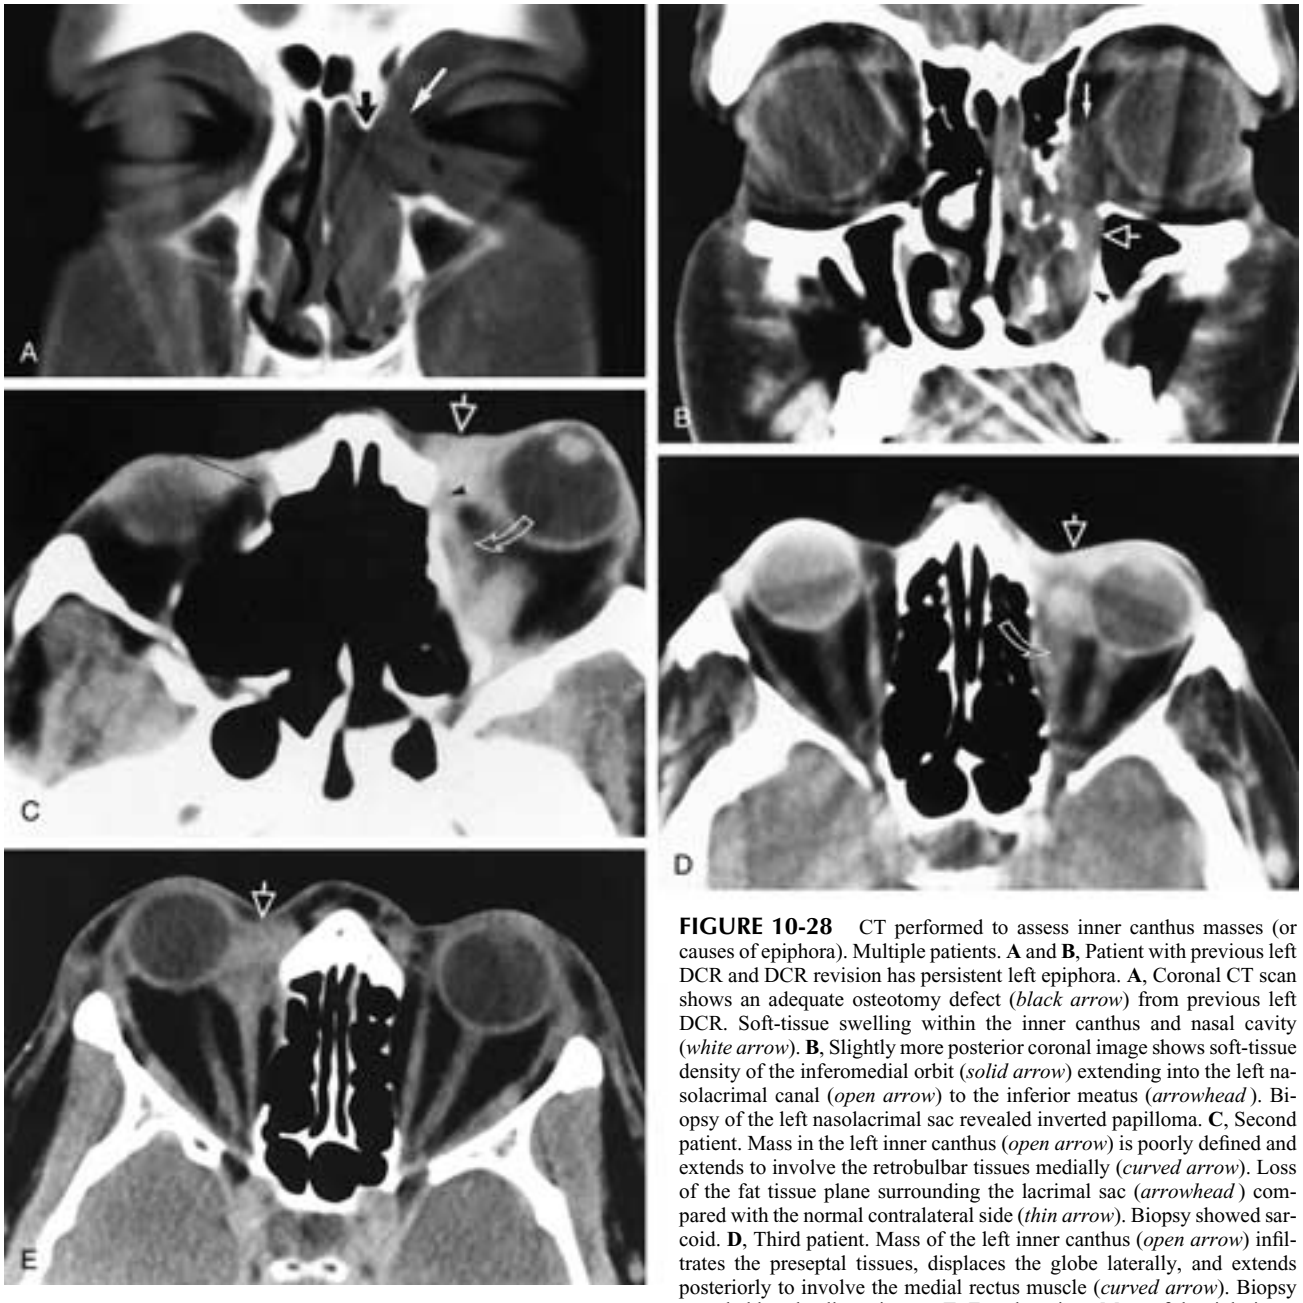

FIGURE 10-28 CT performed to assess inner canthus masses (or causes of epiphora). Multiple patients. **A** and **B**, Patient with previous left DCR and DCR revision has persistent left epiphora. **A**, Coronal CT scan shows an adequate osteotomy defect (*black arrow*) from previous left DCR. Soft-tissue swelling within the inner canthus and nasal cavity (*white arrow*). **B**, Slightly more posterior coronal image shows soft-tissue density of the inferomedial orbit (*solid arrow*) extending into the left nasolacrimal canal (*open arrow*) to the inferior meatus (*arrowhead*). Biopsy of the left nasolacrimal sac revealed inverted papilloma. **C**, Second patient. Mass in the left inner canthus (*open arrow*) is poorly defined and extends to involve the retrobulbar tissues medially (*curved arrow*). Loss of the fat tissue plane surrounding the lacrimal sac (*arrowhead*) compared with the normal contralateral side (*thin arrow*). Biopsy showed sarcoid. **D**, Third patient. Mass of the left inner canthus (*open arrow*) infiltrates the preseptal tissues, displaces the globe laterally, and extends posteriorly to involve the medial rectus muscle (*curved arrow*). Biopsy revealed basal cell carcinoma. **E**, Fourth patient. Mass of the right inner canthus (*arrow*) obscures insertion of the medial rectus into the globe. Biopsy found orbital pseudotumor. (See also Fig. 10-20.)

VIEW IMAGE

and malignant fibrous histiocytomas may present at this location.

Orbital pseudotumor, especially if the medial rectus is primarily involved, can extend from the tendinous insertion to the adjacent lacrimal fossa. Radiographically, pseudotumor may be difficult to differentiate from malignant involvement, especially lymphoma. Sarcoidosis and other granulomatous inflammatory processes occasionally will be localized in the inferomedial orbit or within the nasolacrimal drainage apparatus (Fig. 10-20).

Lacrimal Sac Tumors

Tumors of the lacrimal sac are rare.[165, 170] These include a wide variety of epithelial and nonepithelial tumors (see Table 10-4). Epithelial neoplasms are subdivided histopathologically according to the Ryan and Font classification.[171] Benign epithelial tumors include papillomas (squamous, transitional, mixed) and are subdivided into exophytic or inverted growth patterns: oncocytomas, and benign mixed tumors. Malignant epithelial tumors (carcinomas) include squamous and transitional carcinomas, adenocarcinoma, oncocytic adenocarcinoma, and mucoepidermoid and adenoid cystic carcinomas, as well as poorly differentiated carcinoma and papilloma with carcinoma. Malignancies have been subdivided into those arising de novo or arising within or from a benign papilloma[170] (Fig. 10-13A-C).

There is a 55% malignancy rate for all tumors arising within the lacrimal sac.[170] Most tumors arise from the pseudostratified columnar epithelial lining of the sac. Epithelial tumors therefore predominate, representing 75% of all reported cases, with nonepithelial tumors accounting for the remaining 25%.[172] Poorly differentiated squamous cell (epidermoid) carcinomas, followed by transitional cell and mucoepidermoid carcinomas, are the most common malignancies. Benign epithelial masses, mainly papillomas, occur less than one third as frequently as the malignant epithelial tumors.

Nonepithelial tumors include those of mesenchymal origin (fibrous histiocytoma, hemangiopericytoma, lipoma); lymphoid lesions; reactive hyperplasia or malignant melanoma; granulocytic sarcoma (prior to peripheral blood or bone marrow involvement); and neural tumor. Fibrous histiocytoma and lymphoma are the most common nonepithelial tumors of the lacrimal sac. Fibrous histiocytoma displays varying patterns, fibroblastic to histiocytic predominance, and varying degrees of aggressiveness.

Lacrimal sac tumors present insidiously, with nonspecific symptoms of dacryostenosis or dacryocystitis. The tumors may be undiagnosed for months or years.[173] Treatment for a presumed infection may transiently improve swelling of the lacrimal sac and give a false impression of a clinical response, obscuring the underlying neoplastic disease.

The most common presenting signs and symptoms associated with lacrimal sac neoplasms include epiphora (53% of patients) with a mean duration of 3 years; dacryocystitis (38%, often chronic and irrigates freely); a mass or mucocele of the lacrimal sac (36%)[170]; and extension above the medial canthal tendon.[164] In 43% of patients in the Stefanyszyn et al. series,[170] the tumor was inadvertently found at the time of DCR for presumed

Copyright © 2003, Mosby, Inc. All rights reserved.

dacryostenosis. Bleeding from the puncta, either spontaneously or on applied pressure to the lacrimal sac, or bleeding from the nose was noted in 8% of patients, as an early sign in one patient with melanoma and as a late sign in all other neoplasms. The average duration of symptoms in this series preoperatively was 3 years. In a small percentage of cases, metastatic lymph nodes may be the initial manifestation of a malignant lacrimal sac tumor.[174]

The usual sequence of events with a lacrimal sac tumor begins with epiphora, followed by recurrent bouts of dacryocystitis, development of a nonreducible mass in the area of the lacrimal sac, with eventual extension outside the sac, and, later, in certain cases, epistasis, ulceration over the sac, regional nodal involvement (preauricular, submandibular, cervical) in approximately 28% and metastases.[170, 174, 175] Eyelid and orbital extension, with proptosis and decreased ocular motility, may then be noted in a high percentage of patients with malignant epithelial neoplasm.[174, 175] Signs to complement a high index of suspicion, necessary for an early diagnosis, include a painless, nonreducible, firm mass in the lacrimal sac region, especially if the mass extends superior to the medial canthal tendon,[164, 176] compared to the slightly lower position of the lacrimal sac mucocele associated with chronic dacryocystitis. There is a tendency for melanoma of the lacrimal sac to bleed (punctal or epistaxis) and disperse pigment.[176]

DCG tends to display findings earlier with a distended lacrimal sac and a filling defect, as well as mottled density (intraluminal growth), in conjunction with delayed drainage of the contrast material, when CT may still be negative. In early stages of tumor growth, the lacrimal drainage system will be patent.[176] DCG may be a more effective study for differentiating dacryocystitis from neoplasia and differentiating extrinsic from intrinsic lacrimal sac pathologic processes. CT better displays the extraluminal component of the soft-tissue lacrimal sac mass and its extension into

surrounding tissues, bone erosion, or infiltration of the lacrimal sac fossa, nasolacrimal canal, or adjacent orbit and paranasal sinuses. CT-DCG will offer further information about the lacrimal sac lumen, allowing better assessment of the thickness or irregularity of the lacrimal sac wall (intramural growth) and the nasolacrimal duct than CT alone. MR imaging, with its superior soft-tissue resolution, may better display neoplastic extension of the lacrimal sac tumor into the nasolacrimal canal or into the adjacent soft tissues of the orbit.[177] Because of the desire for both bone and soft-tissue detail, CT usually is the primary modality for assessment, with MR imaging playing an adjunctive role in selective cases.

While benign lesions may allow a local resection, epithelial malignancies tend to grow along the epithelium of the lacrimal drainage system. Cure, therefore is dependent on a wide surgical excision of the lacrimal sac mass and the entire lacrimal drainage system (canaliculi, sac, and nasolacrimal duct), combined with a lateral rhinostomy and radiation therapy. CT remains the preferred posttreatment modality for follow-up of these patients. Persistent epiphora is frequently seen in the postradiation nonsurgical patient (e.g., with lymphoma). Postirradiation nasolacrimal duct stenosis is a frequent complication[178] that may be prevented by the insertion of nasolacrimal stents.[177] Epithelial carcinomas of the lacrimal sac have a recurrence rate of 50%.[171] The overall mortality of those treated with a combination of wide surgical excision and radiation is 37.5%.[174, 179]

CT findings of sac enlargement (dacryocystitis as a complication) should be distinguishable from the findings of solid tumor. Intraductal tumor and its relationship to the nasolacrimal bony canal or nasolacrimal fossa is best seen on CT, which also allows extracanalicular tumor spread to be assessed.[70] Bone destruction of the lacrimal fossa is common with intraductal malignant neoplasms.[152] DCG alone or in combination with CT may help better define small tumors arising from the lacrimal sac fundus or show the lumen irregularity caused by the tumor.[180]

FIGURE 10-29 *Continued.* **I** and **J**, Coronal CT scans shows lateral displacement of the lamina papyracea and lacrimal fossa bed, as well as inflammatory changes of the lacrimal sac and surrounding tissues (*arrow*), with loss of normal tissue planes. Pathology: dacryocystitis secondary to anterior ethmoid inflammatory disease—mucocele. **K** and **L**, Fifth patient. Axial and coronal CT scans show a distended lacrimal sac with thickened walls, extensive preseptal swelling, and loss of adjacent tissue planes (*arrow*). Incidental right frontal lobe encephalomalacia. Pathology: lacrimal sac abscess.

Granulomatous pseudotumors, sarcoidosis, or other less common inflammatory or infiltrative diseases may involve the lacrimal sac and should be considered in the differential diagnosis.[181]

Facial Trauma

Traumatic lacerations of the canaliculi are poorly visualized by CT, and if clinical assessment is indefinite, DCG is the definitive study (Fig. 10-31). Similarly, CT may be insufficient to differentiate NLDS obstruction caused by acute edema or ecchymosis of adjacent tissues.[173] Persistent tearing (after subsidence of soft-tissue swelling) or recurrent dacryocystitis suggests a probable obstruction of the nasolacrimal duct system (NLDS) and the need for further assessment.

Fractures of the lacrimal fossa and nasolacrimal canal may lead to an acute and/or delayed obstruction of the nasolacrimal system. Such fractures or bone displacements are best assessed by CT, which may also help prevent a closed manipulation of a sharp, displaced fracture fragment that could further harm the lacrimal sac or duct. Demonstration of such bone fragments suggests that exploration and open reduction is a more prudent treatment.

Approximately 85% of obstructions associated with trauma occurred at the junction of the lacrimal sac and nasolacrimal duct. CT may suggest the level of obstruction by noting the location of fracture fragments. However, DCG remains a more exact and definitive method for locating the point of obstruction.

There is a relative infrequency of epiphora associated with severe facial trauma.[182] Campbell[9] noted only a 12% incidence in 100 cases of central midfacial fractures and postulated several reasons. In both the cranofacial (LeFort III)- and pyramidal (LeFort II)-type fractures, the lacrimal fossa and nasolacrimal canal tend to escape the fracture lines centered more superiorly at the nasofrontal suture and extending lateral to the nasolacrimal fossa and canal. The anterior and posterior lacrimal crests deflect the pyramidal fractures superior and then posterior to the lacrimal fossa into the orbital plate of the ethmoid. The transverse (LeFort I)-type fracture usually involves the lateral wall of the nasal cavity immediately above the floor of the nasal fossa, thereby sparing the nasolacrimal canal. Fistulae of the nasolacrimal duct into the maxillary antra may result from LeFort I type fractures.

Several series documenting orbital findings relative to facial fractures have noted symptomatic lacrimal obstruction in 0.2% of nasal fractures, 3.4% of LeFort II or III fractures, and 17% to 21% of nasoorbital-ethmoidal fractures.[182–187] Unger[188] noted that fractures involving the bony nasolacrimal fossa and canal were associated with simple unilateral facial fractures as well as the more complex midface fractures. Three patterns of fractures were noted: avulsion of the lacrimal sac fossa, comminuted fractures of the lacrimal

VIEW IMAGE

sac fossa or nasolacrimal canal, and linear fractures of the nasolacrimal canal. Fractures involving the nasolacrimal fossa most commonly were avulsions of an intact nasolacrimal fossa, with comminution of the nasolacrimal fossa being less frequent. Linear fractures of the fossa are rare. The anterior (frontal process of the maxilla) and posterior (lacrimal bone) lacrimal crests fortify the nasolacrimal fossa such that it maintains its integrity when displaced from the more fragile components of the adjacent orbital and nasal structures.[188] This CT finding correlates with the clinical observations that direct lacerations of the lacrimal sac are rare and that obstruction at the junction of the lacrimal sac and nasolacrimal duct is common.[189]

Although the superior aspect of the nasolacrimal canal is also formed by the lacrimal bone and maxilla, most of the canal continues within the medial (nasal) wall of the maxilla, which progressively thins toward the nasolacrimal canal opening just inferior to the inferior turbinate. The majority of fractures involving the nasolacrimal canal are comminuted, with the comminution being more common and more extensive where the bone is thinner at the more inferior aspect of the canal. Linear fractures of the nasolacrimal canal are relatively uncommon. Complication of drainage (epiphora) was seen in only 5 of 25 patients.[188]

Previous facial fracture repairs may add complexities to the performance of lacrimal surgery.[189] Bone grafts used in reconstruction may alter anatomic landmarks.[183, 190] Metallic plates, wires, and silastic or mesh sheets used for fracture repair may impede the lacrimal surgery or be causative factors in the lacrimal drainage symptoms and may require removal during the surgical repair or DCG.[183, 190] CT remains the primary modality of investigation for assessing facial fractures, malalignments, residual deformities, previous instrumentation, and their relationship to the NLDS. CT can also be used to show the bony anatomy in patients after surgery such as DCR (Fig. 10-32).

COMBINED CT-DACRYOCYSTOGRAPHY

DCG is the best modality to demonstrate obstruction of the NLDS itself, and CT is valuable in imaging the surrounding bone and soft-tissue structures of the face, sinuses, and orbit. Conventional CT alone cannot provide

adequate information to suggest a focus of obstruction in the epiphora patient. Combining these two modalities shows the relationship between the NLDS and the surrounding soft tissue or bony structures to better advantage. This combined study (CT-DCG) is indicated in the assessment of more complex lacrimal problems such as medial canthal tumors, midface trauma, or previous lacrimal or adjacent sinonasal surgery (Figs. 10-13 to 10-15, 10-18, 10-19, and 10-27). The combined study can more confidently show masses to be intrinsic (e.g., dacryolith) or extrinsic to the duct system, and the full extent of an extrinsic mass can be more properly defined during CT-DCG. Either axial or coronal imaging may be preferred. Frequently these views are complementary. The continuing advances of spiral (volumetric) imaging with thinner overlapping slices allow improved image data accumulation in the axial plane. Reconstruction capabilities allow selective sagittal or coronal oblique images exactly along the axis of the NLDS. Reformatted studies reduce the total radiation exposure for such studies compared to direct imaging in multiple planes.

CT-DCG may better demonstrate the exact relationship of the lacrimal sac to the paranasal sinuses and advise the

surgeon whether the ethmoid sinus will be encountered in the course of the dacryocystorhinostomy (DCR). The most anterior ethmoid cells, the agger nasi cells, extend into bone adjacent to the lacrimal sac in 94% to 98.5% of patients, overlying the superior half of the lacrimal sac fossa.[191] Inappropriate osteotomy placement or inadvertent anastomosis of the lacrimal sac to an ethmoid air cell, rather than to the nasal mucosa, can lead to DCR failure.[191–193]

The location of the bony opening in patients who have undergone previous unsuccessful DCR is frequently invisible on DCG, but this surgically important information may be attained by CT-DCG.[194] Welham and Wulc's study[112] of 208 DCR failures, problems with the bony ostium were present in over half of the cases and represented the most common cause of DCR failure. Glatt et al.[194] emphasized the use of CT-DCG to show the relationship between the bony ostium of the failed DCR and the lacrimal sac, filled with radiographic contrast medium. Improper placement of the ostium, including too anterior, too inferior, or too small (improper size), was noted in their study. A proper osteotomy for external DCR should be relatively large, measuring at least 15 mm in diameter, all bone between the lacrimal sac and nasal mucosa should be removed, and no bone should be left within 5 mm of the common canaliculus.[24, 107, 112] A smaller bony ostium (5 to 7 mm in diameter) may be successful and appropriate for a transnasal laser DCR.[195] Bone regrowth at the osteotomy site after DCR is unusual, but may occur in children and can be a cause of DCR failure at the osteotomy site.[112] CT-DCG may show bone regrowth between the lacrimal sac and nasal cavity. Linberg et al.[196] showed that the average diameter of the intranasal ostium postoperatively shrinks to 2% of the original operative diameter, mainly because of soft-tissue scarring. CT or CT-DCG with proper use of bone and soft-tissue windows facilitates reoperation after DCR failure by determining what modifications are required in the bony ostium.[194] Such studies can also show whether anterior ethmoid air cell resection is required to allow proper mobilization of lacrimal and nasal mucosal flaps and appropriate internal anastomosis and drainage into the nasal cavity. Similarly, anatomic variants of the nasal cavity, anterior middle turbinate, inferior turbinate, or nasal septum may be noted. CT-DCG best shows the relationship of surgical clips, sutures, and fixation plates to the nasolacrimal sac or the osteotomy site. On routine intravenous enhanced CT or during surgery, it may be very difficult to identify the lacrimal sac on DCR failure patients because of exuberant granulation tissue or scarring and attenuation of anatomic landmarks. Such soft-tissue proliferation at the internal anastomosis may represent inadequate mucosal end-to-end suturing between the lacrimal sac and the nasal cavity.[112] CT-DCG facilitates the treatment of these more difficult patients by identifying the lacrimal sac's shape, location, and relationship to surrounding structures, especially the ostium and/or surgical clips. The more recent transnasal endoscopic approach to DCR failures requires knowledge that the bony ostium is of adequate size and location before considering this approach.

CT-DCG was more sensitive than MR-DCG in differentiating high-grade stenosis from total obstruction of the NLDS.[151] In the presence of postoperative scarring, MR-DCG was less helpful in assessing the site and size of a bone defect after rhinostomy. CT-DCG is preferred for such patients, better differentiating soft tissue from bone obstructions. Epiphora is a common complication following medial maxillectomy for lateral nasal wall neoplasms. Outlining the NLDS with contrast, in conjunction with CT, may better assess patients with poor lacrimal drainage and may differentiate possible causes including residual tumor, inflammatory changes, fibrosis, and postsurgical or postradiation effects on the sinus, the nasal cavity, or the NLDS itself.

In patient with a lacrimal outflow symptoms after trauma, CT-DCR offers all the advantages of routine CT with the additional benefits of more exact localization of the lacrimal drainage system. CT-DCR can assess the possible complexities of the lacrimal surgery (usually DCR) resulting from distorted anatomy secondary to trauma or previous reconstructions including grafting. Adjacent anatomic variations (anterior ethmoid air cells, proximity of the anterior middle turbinate process, or deviated nasal septum) are visualized, as are the locations of previous placed miniplates, wire, or silastic sheets that may need to be removed because of interference with lacrimal flow.[51]

Ashenhurst et al.[197] performed CT-DCG immediately following standard intubation macro-DCG. They left the DCG lacrimal cannula in place, with contrast medium reinjected just before CT scanning (Fig. 10-27). Images were obtained in the coronal and/or axial plane, depending on clinical and DCG information. Glatt et al.[194] similarly used an oil-based radiopaque contrast medium injected via an inferior canalicular catheter insertion and recommended CT-DCG immediately following the injection of contrast. In the assessment of failed DCRs, they found coronal images to be more helpful. Imaging should be obtained in both bone and soft-tissue modes for proper assessment of the soft tissues and adjacent bony landmarks. CT-DCG can be performed using water-soluble contrast medium eye drops placed into the conjunctival cul-de-sac.[23, 197–200] Although such topical application of contrast material may be less predictable in demonstrating the NLDS than cannulation CT-DCG, several advantages may be realized. Topical CT-DCG allows a more physiologic evaluation of the NLDS and increases patient comfort, tolerance, and acceptance of the study. The ease of the procedure obviates the need for skilled personnel to perform the lacrimal cannulation and eliminates any risk of procedural iatrogenic injury from the cannulation or injection of contrast medium. The increased sensitivity of CT for detection of subtle attenuation changes of contrast medium within the NLDS has allowed the option of decreased volumes and concentrations of such agents. The topically applied contrast used is low-osmolar, nonionic, and water soluble, with a concentration of 200 mg I/ml. One to two drops per minute, per eye, is given for 2 to 3 minutes before actual scanning starts. The patient is kept in a supine position for axial imaging or turned prone just before direct coronal imaging.

In a study[199] comparing instillation of topically applied contrast agents into the tear lake, iopamidol (Isovue 200; Squibb Diagnostics, Princeton, New Jersey) for CT and normal saline for MR-DCG, in healthy normal volunteers, CT-DCG consistently better displayed the smaller components of the NLDS (e.g., the superior, inferior, and common canulicula) than MR-DCG. These structures were seen

Copyright © 2003, Mosby, Inc. All rights reserved.

routinely on CT-DCG, while MR-DCG displayed the superior and inferior canulicular structures in approximately 50% and the common canaliculus in less than 20%.

While a variety of CT-DCG techniques allows personal preference and comfort, certain circumstances require techniques that are more specific. Routine placement of drops of contrast medium into the conjunctival cul-de-sac (tear lake) may offer inadequate visualization of the NLDS in those patients with known punctal or canalicular stenosis, other higher-grade stenoses, or conditions not favoring the flow of such contrast into or through the NLDS. For these patients, a less physiologic and more anatomic placement of contrast through cannulation is required. While some individuals may prefer the more pronounced attenuation of lipid-based contrast agents (e.g., Lipiodol ultrafluide; Guerbet, Villepinte, France), caution with the use of such agents is imperative. Their increased viscosity makes placement into the conjunctival sac impractical. Lipid-based contrast medium introduced through cannulation is more at risk for extravasation and related long-standing complications,[201] especially in the posttraumatic study or in assessing the patient with chronic inflammatory tissues of the NLDS. We routinely use water-soluble, low-osmolar contrast, with excellent results and increased safety. This approach provides excellent images. This CT-DCG technique better demonstrates the canaliculi of the upper drainage system (Fig. 10-19) than cannulation CT-DCG and offers further advantage when used with spiral (helical) CT and its volume data acquisition,[198–200] offering coronal and sagittal oblique reformations of superior quality along the axis of the NLDS. The extremely fast total data acquisition times (less than 20 to 30 seconds) ensures patient cooperation and almost no risk of movement, despite the acquisition of very thin (1 mm or less) overlapping axial scans through the area of interest. The high-quality reformations obviate the need for direct coronal imaging. Three-dimensional images of the NLDS can be reconstructed using a connectivity algorithm and viewed in relationship to adjacent orbital or facial skeletal structures. Patients may complain of slight dryness, burning, or irritation of the eye from the topical administration of water-soluble contrast material.[23, 199]

Pediatrics

Congenital Atresia

The nasolacrimal apparatus develops from a core of surface epithelium, the nasooptic fissure, trapped between the maxillary and frontonasal processes. Although canalization occurs uniformly throughout the length of the nasolacrimal drainage system, failure in this process is most common at the distal nasolacrimal canal. There is lack of perforation of the nasolacrimal canal at the inferior meatus (valve of Hasner), with a persistent layer of lacrimal and nasal epithelial cells, related to adhesions between the nasal mucosa and the nasolacrimal epithelium.[202] In some patients, a plug of epithelial cell debris causes obstruction.[203] Such distal obstruction may result in epiphora and mucoid discharge.[204]

Simple inspection allows diagnosis of congenital atresia of the lacrimal puncta. If only one punctum is involved, DCG should be performed through the opposite punctum to visualize the canaliculi. Retrograde filling of the canaliculus without reflux through the punctum indicates focal occlusion. If the canaliculus fails to visualize, there is atresia of the entire canaliculus.[88]

Congenital obstruction of the NLDS occurs commonly, but significant symptoms are relatively rare. Sevel[202] noted an incidence of NLDS obstruction in 30% of term fetuses and MacEwan and Young[205] noted such obstruction to be a common clinical problem, affecting as many as 20% of all infants, while Levy[206] noted epiphora occurring in only 6% of infants. Increased intraluminal pressure in the duct during initial respiratory efforts or crying at birth may rupture the distal membrane, forming the one-way valve of Hasner.[207, 208] These findings may partially explain the high proportion (85%) of spontaneous resolution of NLDS obstructions before the child reaches age 9 months.[209] The low rate of tear production during early infancy is also a factor in the low incidence of epiphora.

Rarely, concomitant obstruction is also present more proximally in the NLDS, creating a closed space that allows accumulation of fluid, causing a cystic swelling of the NLDS (Fig. 10-33). Such proximal obstruction occurs as the result of a valve-like unidirectional obstruction at the junction of the lacrimal canaliculi and sac (valve of Rosenmüller).[27] Cystic swelling may also result from some component of active intraluminal secretions. Berkowitz et al.[204] prefer the term *congenital nasolacrimal drainage system cyst* for this cyst, seen as a bluish mass below the medial canthal angle. The terms *mucocele*, *dacryocystocele*, and *amniotocele* are also applied to this entity. If a distended lacrimal sac is present at birth, without associated inflammatory changes, the cystic swelling is referred to as an *amniotocele containing sterile amniotic fluid*.[27] If the cyst is filled with epithelial debris and mucus generated by the NLDS, the term *mucocele* may be used.[208] Compression of the distended lacrimal sac does not tend to cause regurgitation through the puncta.[210] Conservative management is generally preferred. Probing may prevent dacryocystitis or pressure on the globes. Surgical intervention (usually probing only) is generally not recommended unless complications develop or obstruction persists after age 6 to 9 months. Complications of a congenital nasolacrimal cyst include epiphora, dacryocystitis, cellulitis, sepsis, and respiratory distress.

Cystic distention of the lacrimal sac expands the nasolacrimal fossa by pressure erosion, accentuating the posterior lacrimal crest. Nasal extension may cause respiratory distress. Probing of the nasolacrimal duct system, with relief of proximal and distal obstructions as initial treatment, may relieve respiratory distress.[211] However, intranasal marsupialization of the cyst is usually recommended if there is nasal airway compromise. Berkowitz et al.[204] suggest that NLDS cysts may be more common than was previously thought and that any neonate showing signs of NLDS obstruction should have a careful nasal examination to rule out an associated nasal mass. Obstruction to the NLDS may be an unrecognized cause of transient nasal mucosal congestion in the newborn.[204]

CT may help show the classic triad of a cystic medial canthal mass, dilation of the nasolacrimal duct, and a contiguous submucosal nasal cavity mass in the inferior meatus.[212, 213] Endoscopy may show this submucosal

VIEW IMAGE

soft-tissue mass in the inferior meatus. Multiplanar MR imaging may better show the skull base and is useful in detecting findings that suggest other causes of medial nasoorbital mass lesions such as meningoceles, encephaloceles, and nasal gliomas. The presence of the classic triad suggests a congenital cyst or mucocele of the nasolacrimal duct, that is, a more distal duct obstruction. Obstructions that are more proximal tend to produce a lacrimal sac mucocele. However, mucoceles of the nasolacrimal duct system may extend either cranially or caudally; that is, mucoceles of the lacrimal sac may protrude downward into the nasolacrimal duct while mucoceles arising in the duct may extend upward to involve the lacrimal sac.[212] Mucoceles involving the lacrimal sac will have, as a clinical component, a mass in the medial canthus. Mucoceles of the distal nasolacrimal duct may present with cyst-like masses at the anteroinferior nasal cavity with a normal lacrimal sac and a superior nasolacrimal duct, because kinking of the thickened, inflamed mucosa in the upper portion of the mucocele prevents extension of secretions (or the mucocele) into the more proximal lacrimal apparatus.[212] The absence of a medial canthal mass therefore does not rule out obstruction of the NLDS or the diagnosis of a congenital NLDS cyst.

A variety of treatments have been described for congenital lacrimal system obstructions including massage (local), probing, irrigation, silicone intubation, and DCR. Although there is no consensus about the timing of or requirement for nasolacrimal probing, such probing is generally successful for treatment of nasolacrimal duct obstruction.[202, 214] However, the rate of failure of probing increases after the patient reaches 12 months of age. After 24 months of age, probing may fail in 67% of patients, and procedure-related complications increase significantly.[214, 215] Silicone intubation may be effective in those children in whom probing has failed; however, this technique also has associated complications such as laceration and erosion of the canaliculi, granuloma formation, corneal erosion, punctal injury, or premature intubation removal.[216] Formerly, DCR became the necessary procedure if silicone intubation failed. More recently, balloon dilation of the nasolacrimal system has been offered as a safe, effective alternative treatment for congenital nasolacrimal drainage obstruction, either as a primary procedure or after failure of probing or silicone intubation.[217, 218] Becker et al.[217] noted an overall postdilation patency rate of 95%, but the study had a limited follow-up period of 4 to 10 months.

Cho et al.[218] recently reported their hospital's treatment of 36 pediatric patients, older than 12 months of age, with congenital lacrimal system obstruction, 16 of whom had fluoroscopically guided balloon dilation (mean age, 33 months). Obstruction was most frequent at the valve of Hasner (15 eyes), with obstruction at the nasolacrimal duct in 2 eyes and at Krause's valve (junction of the lacrimal sac and duct) in 3 eyes; all but 2 eyes had complete obstruction. Seventy percent had had previous treatment with probing, irrigation, or silicone intubation (mean age, 34 months). The authors had a technical success rate (defined as free passage of contrast medium through the entire nasolacrimal system to the nasal cavity) in 95%, with clinical success (resolution of epiphora) in all patients in whom technical success was

Copyright © 2003, Mosby, Inc. All rights reserved.

achieved (mean follow-up of 16 months). Becker et al. performed balloon dilation through the superior canaliculus in an antegrade method after puncturing the obstruction with a probe, while Cho et al. used a retrograde approach, to better avoid canalicular damage, after puncturing the obstruction with a relatively stiff ball-tip guidewire. For both groups of authors, the results of balloon dilation in congenital nasolacrimal system obstruction were far more successful than dilation in adult nasolacrimal obstruction.[219–221] This is probably explained by the differences in pathogenesis. The majority of congenital obstructions are related to developmental anomalies such as a thin, persistent layer of nasolacrimal and nasal epithelial cells at the valve of Hasner.[106, 202, 203, 218] Such anomalies respond well to balloon dilation, with a low incidence of reobstruction secondary to adhesions and fibrosis, in contrast to the epiphora in adults caused by acquired etiologies such as chronic infection and/or inflammation, chronic fibrosis, involutional stenosis, or constriction secondary to the aging process. The one technical failure in Cho et al.'s series was in a patient with obstruction proximal to the valve of Hasner and may have represented a more diffuse nasolacrimal duct stenosis. (See also the section on Dacryocystoplasty and Stent Placement.)

Duplication

Canalicular duplication is usually asymptomatic. DCG will show the supernumerary duct as an opacified streak close to the superior or inferior canaliculus.[88]

MAGNETIC RESONANCE DACRYOCYSTOGRAPHY

Routine MR imaging, with or without intravenous gadolinium, may show disease processes, whether inflammatory or neoplastic, invading the region of the nasolacrimal duct system (NLDS) and the medial canthus. MR imaging was not utilized to assess intrinsic abnormalities of the NLDS proper (canaliculi, lacrimal sac, or nasolacrimal duct), although it could detect significant dilatation of the lacrimal sac or nasolacrimal duct (Figs. 10-20, 10-26, and 10-30). Conventional NLDS contrast media for DCG, whether oil based or water soluble, tended to be viscous and were routinely introduced by cannulation. Although oil based contrast can be identified within the NLDS by its specific fat intensity signal on MR imaging, the inconvenience of cannulation, the increased viscosity and poor miscibility of such contrast agents with tear fluid, and the risks of granuloma formation if extravasation occurs limit the use of MR imaging for assessment of intrinsic nasolacrimal drainage pathology. MR imaging has maintained a complementary role to Digital Subtraction DCG (DS-DCG), with DS-DCG assessing the NLDS and MR/CT assessing the adjacent extraluminal soft tissues. The increased soft-tissue resolution of MR imaging and the anterior location of the NLDS allowing surface coil imaging favor the strengths of MR imaging. In 1993, Goldberg et al.[222] utilized gadolinium (gadopentetate dimeglumine [Magnevist]; Berlex Laboratories, Wayne, New Jersey) in a diluted state, either topically or by cannulation, to visualize directly the canaliculi, lacrimal sac, and nasolacrimal duct. The gadolinium solution, initially diluted 10:1 in sterile saline, was further diluted 10:1 in a commercial liquid tear preparation such as methylcellulose. The prepared 1:100 solution represented a 0.5% concentration or 300 mOsm/L of gadolinium (from the initially commercial available 48.0% concentration). Used topically, the solution was introduced as an eyedrop into the conjunctival cul-de-sac, one drop per minute for 5 minutes immediately prior to scanning, with the patient in a supine position (Fig. 10-34). The authors recommended obtaining imaging within 5 to 10 minutes of introduction of the gadolinium solution. The contrast agent remains within the drainage system for approximately 20 minutes.

More recent studies[223] also suggest an interval of approximately 5 minutes between the final instillation of topical contrast into the conjunctival cul-de-sac and initial imaging to allow adequate passage of contrast through the NLDS (the time interval can be used for coil positioning, system tuning, localizer measurements, etc.). Blinking was encouraged between sequences since eyelid movements affect the lacrimal pump and tear transport.[141, 224] The required data acquisition of various sequences, including pre- and postintravenous contrast sequences, allows approximately 15 to 20 minutes for contrast medium distribution and visualization.

Rubin et al.[225] diluted gadolinium with sterile water to a 300 mOsm/L concentration for direct lacrimal sac infusion. Kirchhof et al.,[19] in an attempt to keep the viscosity of the eyedrops low, used saline instead of methylcellulose in the diluted gadolinium solution. They noted an accelerated passage of the eyedrops through the drainage system, making it difficult to trace the contrast agent in a patent nasolacrimal duct system.

Although topically applied gadolinium can assess functional outflow, canalicular injection of 1 ml of 0.5% gadolinium, using a lacrimal cannula, may be indicated in specific patients. The gadolinium solution in a 0.5% concentration is nonirritating to the ocular surface. MR-DCG has the potential to present information about the NLDS and the adjacent soft tissues, with superb soft-tissue resolution. DS-DCG, however, remains the gold standard for assessing the lacrimal drainage system. MR-DCG may be considered in patients with medial canthal masses or more complex tearing disorders, including congenital, postsurgical, or posttraumatic nasolacrimal obstruction or in those cases where a neoplastic process is suspected, either originating in the NLDS (lacrimal sac), adjacent paranasal sinuses, or orbit.[200, 222, 225] However, some suggest a role for MR-DCG in the assessment of the NLDS because DS-DCG fails to delineate the surrounding soft tissues and MR-DCG has increased sensitivity for detection of contrast more distally within the drainage system. MR-DCG does give detailed functional and morphologic information on the NLDS in a simple, noninvasive manner that does not use ionizing radiation. Newer MR-DCG techniques may be useful for depicting nasolacrimal obstruction, utilizing saline or water, without the use of chemical contrast media.[19, 199, 223, 226, 227]

In a study comparing DS-DCG and topical gadolinium-enhanced MR-DCG, Kirchhof et al.[19] found 100% sensitivity for demonstration of obstruction of the NLDS with either modality. The location of the obstruction was more precisely

FIGURE 10-34 *Continued.* **F** and **G**, Second patient. Topical saline used as contrast medium. One or 2 drops per minute instilled into the conjunctival sac for 4 to 5 minutes prior to scanning may better demonstrate the lumen of the NLDS (*arrows*) on axial (**F**) and coronal (**G**) T2-weighted sequences. The saline flows more quickly through the drainage system than topical gadolinium, especially if the gadolinium is partially diluted with artificial tear drops.

detected on MR-DCG, with the contrast material traced further distally with MR-DCG than with DS-DCG in 3 of the 11 patients. MR-DCG, however, like other imaging modalities, may also diagnose NLDS obstruction too proximal due to accumulation of thickened mucus within the duct system. This problem may be avoided by performing irrigation and careful expression of the lacrimal sac prior to any DCG-type, contrast-enhanced NLDS imaging study. In contrast to the increased signal of contrast medium, mucus was isointense with mucosa on T1-weighted images and slightly hypointense on T2-weighted images. A fluid-fluid level may be seen between the contrast agent and mucus on coronal T1-weighted images.[19] MR-DCG may better distinguish soft-tissue obstruction from bone obstruction, a factor in deciding whether dilatation of a stenosis (dacrycystoplasty) is feasible or whether a surgical procedure (DCR) will be needed.

MR-DCG may better assess the amount of lacrimal sac mucosa present and available for mucosal flap manipulation (lacrimal sac to nasal mucosa anastomoses needed for external DCR surgery), with normal sac mucosa well delineated on T2-weighted, fat-saturated sequences. Although both DS-DCG and MR-DCG displayed the obstruction of the lacrimal sac 1 year after DCR in one patient, only MR-DCG directly displayed the postoperative cicatricial scarring.[19] DS-DCG and MR-DCG were equivalent in assessing size and filling defects within the lacrimal sac, a factor of importance for endoscopic intranasal DCR considerations, since scarring and dacryolithiasis are significant prognostic factors and potential contraindications. DS-DCG was superior in only one patient in whom MR-DCG failed to delineate fistulas distal to the nasolacrimal sac.[19]

Fat-saturated MR imaging sequences were preferred, with T2-weighted images considered superior to T1-weighted and with the fat-saturated sequences allowing better visualization of the contrast agent. Coronal slices (obtained at 70° to the hard palate to be parallel to the course of the lacrimal sac–nasolacrimal duct) were considered more helpful. Axial images were complementary and were preferred for measurement of the lumen of the lacrimal sac or nasolacrimal duct.[19] Acknowledging the additional information about the surrounding soft tissues, Kirchof et al.[19] noted that both MR-DCG and DS-DCG reliably depicted obstructions of the NLDS, but because of the increased expense of MR-DCG and the limited experience in differentiating between obstruction and stenosis of the NLDS, DS-DCG should be the first imaging study. MR-DCG should function as a complementary study except in the pediatric age group. In epiphora patients under age 6, MR-DCG, noninvasive and free of radiation, can be performed with sedation only (in contrast to DS-DCG, which is performed under general anaesthesia) and should be the primary imaging modality for assessment.

In Caldemeyer et al.'s[199] study of CT-DCG and MR-DCG utilizing topical contrast material, CT-DCG, with iopamidol (Isovue 200; Squibb Diagnostics, Princeton, New Jersey) and MR-DCG with normal saline, respectively, placed into the conjunctival cul-de-sac of healthy normal volunteers, CT better displayed the finer drainage system components better than MR-DCG. CT also displayed the adjacent bone anatomy.

In a study comparing DS-DCG and MR-DCG, Yoshikawa et al.[226] concluded that topical contrast-enhanced MR-DCG by itself may not be sufficient when precise information, including the length of the stenosis and the degree of narrowing is necessary to plan for DCG or nasolacrimal stenting. MR-DCG findings were not compatible with DCG findings in half of the 14 patients. On initial phantom studies, all sequences could visualize ducts equal to or smaller than 0.7 mm in diameter filled with contrast material. The lower spatial resolution of MR-DCG (11 cm rounded receiving surface coil, body coil for transmission) compared to DS-DCG and the absence of pressure (topical application) may result in an overexpression of stenosis or in interpreting stenosis as an obstructive lesion.[226] Cannulation MR-DCG may help eliminate these limitations.

Copyright © 2003, Mosby, Inc. All rights reserved.

Hoffman et al.[223] noted difficulties in detecting contrast medium (diluted gadolinium topically placed) in the most distal part of the NLD in some patients with mild epiphora, yet there was filling of the lacrimal sac and proximal duct. They postulate a physiologic obstruction at the distal end of the nasolacrimal due to resistance of the valve of Hasner. Similar findings have been previously noted in DSG,[144] with long transport delays (30 minutes or longer) even in asymptomatic eyes. Circumstances causing increased production of tears or minimal narrowing of the nasolacrimal duct may contribute to epiphora. The marked variation in tear transport times limits the assessment of the functional MR-DCG exam and must be interpreted with clinical and other imaging findings. For these reasons, DCG remains the standard exam for assessing obstructions of the NLDS.[223]

Recent MR-DCG studies have assessed other solutions (with associated MR technique alterations) to augment or possibly replace gadolinium as a contrast agent.[199, 226, 227] Yoshikawa et al.[226] combined T1-weighted (transverse thin slice) spin-echo and 3D-T1 fast field echo (FFE) sequences utilizing a topical diluted gadolinium solution, (with reconstructed Maximum Intensity Projection (MIP) images projected in the anteroposterior direction for the 3D-FFE sequence) as well as two T2-weighted sequences. The T2-weighted sequences included a transverse thin-slice fast spin echo (FSE) sequence and a coronal thick-slice section T2-weighted projected image, with the coronal sequences utilizing a topical saline solution rather than the diluted gadolinium solution. MR-DCG diagnoses were made by combining the findings on the saline-enhanced T2-weighted and gadolinium solution-enhanced T1-weighted images. The transverse images confirmed the diagnosis from the projected images. If discrepancies were noted between the T2-weighted projected images on the FFE-MIP images, the narrowed site was determined by the gadolinium-enhanced FFE-MIP images. In a preliminary study of 10 normal volunteers, the lacrimal sacs and proximal portion of the nasolacrimal ducts were seen in all patients; however, the caudal aspects of the nasolacrimal ducts and the canaliculi were not visualized on most sequences in approximately half of the cases. The inability to visualize the caudal portions of nasolacrimal ducts in normal volunteers may be due to the relatively fast flow in the narrowing lumen of the caudal duct or to an increase in the viscosity of the intraluminal fluid. The long echo time of the T2-weighted projected images may need to be adjusted to each patient's circumstance and may limit the discrepancies seen between the T2-weighted projected images and the FFE-MIP images. In the clinical study, inconsistent findings were also noted between the T2-weighted projected images and the FFE-MIP images or with the DS-DCG findings.[226]

The lacrimal sac residual lumen volume and the condition of the mucosa were better seen on the T2-weighted sequences. Mucosal thickening, including low signal intensity mucosal fibrous thickening, was noted on T2-weighted sequences, with intravenous gadolinium-enhanced images offering further information if required. The T2-weighted sequences also displayed the residual caudal lumen of an obstructed or narrowed site, which may help predict the effectiveness of conservative treatments (e.g., irrigation therapy). Despite limitations, combined complementary T1- and T2-weighted sequences, with respective diluted gadolinium or normal saline solutions as a less invasive study, may offer enough morphologic and functional information in the NLDS to have a screening role or potential to be the imaging examination of first choice for patients with lacrimal outflow disorders.[226]

Takehara et al.[227] have implemented MR-DCG techniques utilizing a less viscous combined normal saline–lidocaine hydrochloride solution as a contrast medium to emphasize the dynamic behavior of the fluid within the lacrimal pathway. The authors performed all studies via thin plastic lacrimal cannulas placed into the inferior lacrimal canaliculi bilaterally, with a Y-connector allowing bilateral simultaneous injection. Axial and coronal T2-weighted images were obtained using FSE or half Fourier single-shot FSE sequences without fat saturation. With the patient already in place within the gantry, the dynamic MR-DCG was performed while the patient injected the previously prepared combined saline-lidocaine solution by manual compression of the barrel of a single syringe. Thick-slice (20 to 30 mm), heavily T2-weighted images were repeatedly obtained during the injection. The section of study included the canaliculi, lacrimal sac, and nasolacrimal duct. Acquisition time for each image was less than 2 seconds. During the injection, imaging was repeated for 3 minutes with intervals of 4 to 5 seconds. Overall MR imaging time, including that for preliminary conventional T1- and T2-weighted sequences, was less than 20 minutes.

The solution's lower viscosity better filled the narrowed lumen of the NLDS. MR-DCG can be monitored and viewed during the course of the injection, so the patient can be directed to increase the injection rate if filling is incomplete or delayed. MR-DCG offers high temporal resolution, allows dynamic evaluation of fluid flow in the NLDS, and will not potentially miss the image that best demonstrates the obstructive segment. This concept parallels the advantages of DS-DCG compared to radiographic distention DCG and offers a dynamic capability superior to that of CT, without the radiation exposure. Such dynamic assessment, however, requires the facilitating solution to be introduced through lacrimal cannulas. Because of the decreased viscosity of the solution utilized, such cannulas, however, may be thinner and softer, allowing more comfortable, safer cannulation of the canaliculi.

In contrast to other MR-DCG techniques that are stationary or slow-flowing, this MR-DCG uses water injected into the lacrimal draining system as a substitute for other contrast media. The imaging strategy involves the acquisition of a series of heavily T2-weighted images since fluid-filled nasolacrimal ducts have long longitudinal and transverse relaxation times and will display high signal intensity on T2-weighted images. However, on these hydrographic images, everything looks black or white. The nasolacrimal abnormalities are evaluated indirectly using ''all-or-nothing'' images. The FSE sequence used was relatively immune to local magnetic field inhomogeneity (air in the maxillary sinus, dental prosthesis).[227] Dynamic MR-DCG, as a form of hydrographic imaging, does not reflect any soft-tissue contrast. Additional T1- and T2-weighted sequences are required for delineation of soft tissue (e.g., the presence of mucosal thickening or neoplasm). Half Fourier SS-FSE or FSE imaging using multiple thin slices provides static but detailed information. As also

noted in more static MR-DCG studies with saline placed topically into the conjunctival cul-de-sac and imaged with heavily T2-weighted sequences, mucosal disease of the NLDS or adjacent paranasal sinuses can make visualization of the NLDS more difficult.[199] Comparison of images before and after contrast administration is important to distinguish mucosal thickening from normal flow of saline. Image subtraction may be feasible. This technique is probably limited in detecting dacryolithiasis. Further investigations are necessary to assess the true potential and capabilities of dynamic MR-DCG.

DACRYOCYSTOPLASTY AND STENT PLACEMENT

Balloon Dacryocystoplasty

See the previous section on Congenital Atresia for further comments on dacryocystoplasty and stents. A small-bore soft[228] or ball-tip[229] guidewire (0.018 inch diameter) is introduced into the superior punctum and guided under fluoroscopic control through the NLDS into the inferior meatus. With nasal endoscopic assistance or lacrimal instruments and lateral fluoroscopy, the guidewire, which prefers to pass toward the nasopharynx, is directed through the nares. A hook was devised to grasp the guidewire under fluoroscopic control, shortening the procedure time and eliminating the need for nasal endoscopy.[230] A deflated angioplasty balloon catheter is introduced in a retrograde direction over the guidewire (in contrast to Becker and Berry's[231] initial report of antegrade balloon dilation of the nasolacrimal duct's nasal ostium). Proper positioning and dilation are controlled by fluoroscopic guidance, with injection of radiographic contrast media to inflate the balloon catheter (Figs. 10-35 and 10-36). The tibial arterial balloon angioplasty catheter (Cook Inc., Bloomington, Indiana), which dilates to 3 to 4 mm in diameter, is useful for Dacryocytoplasty (DCP). Different methods of dilation have been described, with Munk et al.[228] and Janssen et al.[219] recommending two or three dilations of 20 to 30 seconds each, while Song et al.[220] recommended that each dilation last for 5 minutes. Lee et al.[229] found that the soft tip and lack of tapering of the Balt balloon (Montmorency, France) made it preferable for dilations. After the final dilation, the balloon is withdrawn inferiorly and the guidewire superiorly (to avoid having the stiff segment of the guidewire pass through the area of recent dilation). Song et al.[220] leave the guidewire in place and perform DCG via the inferior punctum to verify passage of contrast medium. Balloon catheters with gradually increasing calibers ranging from 3 to 5 mm may be used. An irrigation of the NLDS with sterile saline, with or without dexamethasone, through the dilation catheter and/or flushing through the superior canaliculus is performed at the end of the procedure. Dexamethasone and antibiotic (gentamycin) eyedrops may be prescribed for 1 week postdilation, as well as acetylcysteine eyedrops if abundant mucus was present in the NLDS.[219] Blood clot formation in the NLDS, especially the dilated lacrimal sac, during or after balloon dilation may be a cause of treatment failure. Song et al.[220] noted such filling defects in 3 of 36 eyes in which DCG was performed immediately following dacryocystoplasty (DCP).

Janssen et al.[219] modified the Munk et al.[228] technique. In cases of complete obstruction in which reflux of contrast medium occurred through the opposite canaliculus, they recommend that DCG be repeated after occluding the noncannulated canaliculus by wedging within it a nonconducting lacrimal catheter. This may allow a small amount of contrast medium to outline an area of stenosis. For the DCP procedures, they favor a nontraumatizing 0.025 inch guidewire with a flexible curved tip (Terumo; Tokyo, Japan) to more easily negotiate the sharp curve between the common canaliculus and the lacrimal sac. Balloon catheter placement is restricted to the lacrimal sac or more caudally to prevent damage to the canaliculi. A balloon catheter with the balloon placed at the catheter tip allows dilation of stenoses high in the lacrimal sac and does not require the catheter tip to be passed into the common canaliculus.[221]

The study is performed under local anesthesia. Patients may experience some mild discomfort in the region of the medial canthus for 1 to 2 days after the procedure and a slightly blood-stained nasal discharge for 1 to 3 days. Evaluation of epiphora may be graded according to a subjective scale, as suggested by Munk et al.[228] This scale has proven useful in allowing comparisons in the epiphora patient population over time, as well as in comparing various patient groups and assessing degrees of success or benefits of treatment. In the system, Grade 0 is no epiphora; Grade 1 is occasional epiphora that requires drying or dabbing less than twice a day; Grade 2 is epiphora that requires drying 2 to 4 times a day; Grade 3 is epiphora that requires drying 5 to 10 times a day; Grade 4 is epiphora that requires drying more than 10 times a day; and Grade 5 is constant tear overflow. There is no standardized definition of success, with some results referring to Grade 0 or Grade 1 as a successful outcome posttreatment, while others may define an improvement of two or more grades as success. Still others may define Grade 2 to Grade 5 as poor outcomes despite improvement in the pretreatment status.

DCP may have a role in a defined patient population. Probing alone is frequently unsuccessful and has a greater risk of creating a false passage. In contrast to dilating probes, the use of balloon dilation offers radially directed dilating forces that are less likely to create severe tears. Fine guidewires of approximately one half the caliber of probes, with soft tips, especially when placed into a strictured or occluded NLDS, offer less risk of complication. Longitudinal shear forces by the larger catheters are reduced by the presence of a guidewire.

DCP is easily performed as an outpatient procedure, obviating the need for general anesthetic or controlled hypotension (used to control hemorrhage) and the relative invasiveness of DCR. More recent performance of DCR surgeries with local assisted anaesthesia and monitored sedation has improved operative field visibility and minimized blood loss while avoiding the hazards of general anaesthesia.[232] Still, the advantages of DCP, with diminished morbidity, cost, and operating room time, are obvious. No facial scarring or disfigurement occurs with DCP, and the procedure, if unsuccessful, does not preclude future DCR.

The use of ionizing radiation for balloon DCP (versus surgical treatment of epiphora) is a disadvantage to be addressed and controlled, to offer minimal radiation exposure since the eye, including the radiosensitive lens, remains in the field of the primary x-ray beam. Mean radiation doses to the lens of the treated eye varied from 1.37 mGy[233, 234] to 4.6 mGy[235, 236] and from 5.43 mGy[233, 234] to 38.5 mGy[235, 236] for the contralateral eye. In both series, the treated eye was always closer to the image intensifier, with the higher mean radiation dose values to the contralateral lens, closer to the x-ray tube. The measured dose to the treated eye may be reduced by limiting the number of digital images obtained. The dose to both eyes, especially to the untreated eye, can be limited by tight collimation, restricted to the treated eye, especially in the posteroanterior images. Phantom studies measured the dose to the untreated lens as only 25% of that to the treated eye (lens) on such collimated posteroanterior images.[233, 234] Much of the DCP procedure is performed using lateral fluoroscopy and digital image acquisition, such that radiation to the contralateral lens cannot be avoided. Approximately 90% of the overall radiation dose to the lens of the untreated eye, closer to the x-ray tube, results from lateral projection versus 65% for the lens of the treated eye.[236] Restricting lateral imaging to fluoroscopy and abandoning such digital image acquisition, the major source of the higher lens dose, will further reduce the lens dose.[236] DCG performed before and after DCP, with the exception of complex cases, should similarly be restricted to posteroanterior projection images.

Although preliminary, Munk et al.[228] experienced very favorable DCP results, with DCPs being technically successful in 16 of 18 cases, with improved epiphora in 13 (complete resolution in 11) patients and no change in 3 patients. Follow-up, however, was limited to 6 months maximum post-DCP, and only four patients had follow-up DCG, all within 3 weeks of the initial procedure. No correlation between degree of epiphora and severity of stenosis on the preprocedure DCG was noted. In the cases of partial stenosis, no change was noted in the appearance of the postdilation DCG, and Munk et al. anticipated that reproducibility of the DCG would be difficult since the nasolacrimal duct, when patent, is an open system, decompressed from below. Munk et al. did not have trouble passing the guidewire in the two cases of complete obstruction. They felt, however, that tight stenosis of the common canaliculus may represent an absolute or relative contraindication to DCP.

Song et al.[220] also noted difficulty defining success (or failure) in interpreting the results. Full dilation of obstructed areas may be noted technically, with the epiphora not resolving. They postulate that placement of stents may be useful in such patients. Song et al.[220, 237, 238] and Lee et al.[229] have followed patients for a more extended period. In further follow-up of those initial successes (in 56% of dilations) assessed at 7 days, 45% showed recurrence of symptoms at 2 months.[220] Although Lee et al. achieved 71% and 51% initial technical and clinical success rates for partial and complete obstruction, respectively, the 2-year clinical patency rates fell to 20% and 25%, respectively. The grade of stenosis did not influence the duration of patency. In assessing their initial results, technical success but clinical failure was noted in 29% and 44% of patients with partial and complete obstruction, respectively, for a 40% overall clinical failure. These patients tended to have clinical improvement of epiphora for 2 to 3 days only. No technical failures were noted in the partial occlusion subgroup, while 5% of those with complete obstruction were technical failures. Dilations of common canaliculus obstructions were more technically difficult. The authors avoided dilation of the superior and inferior canaliculi lateral to the common canaliculus to avoid damage to the canaliculi. Patency rates for complete obstructions remained the same from 6 months to 2 years post-DCP follow-up, while those for partial occlusion decreased such that there was no significant difference between the long-term patency rates of occlusions and stenosis.[229]

Janssen et al.[219] reported 90% substantial success in DCP treatment of 21 nasolacrimal duct system (NLDS) with severe epiphora followed for 14 to 70 weeks. These authors speculate that the finer atraumatic, nonmetallic guidewire (Terumo) and a dilated balloon diameter not exceeding 3 mm (vs. 3 to 4 mm for Munk et al.[228]) and 4 to 5 mm for Song et al.[220] may explain the difference in results. In normal adults, the diameter of the membranous nasolacrimal duct is 4 to 6 mm. Therefore, a larger catheter whose caliber is greater than 3 mm may traumatize the nasolacrimal duct or the rich venous plexus between the membranous portion of the duct and the bony canal.[219]

Continued follow-up of fluoroscopically guided balloon

DCP for recanalization of obstructed NLDS, as a viable alternative to operative treatments, has led to further scrutiny of such procedures due to some disappointing longer-term results, despite its initial technical successes.[219, 220, 228, 229, 239–241]

Various hypotheses have been put forward to improve results. Primary placement of stents, initially in conjunction with balloon DCP[237, 238, 242] and subsequently obviating balloon DCP,[230] were suggested. Others have suggested technique alterations to navigate the difficulties presented by canalicular or upper lacrimal sac strictures. Suggestions have been made to address the challenges of recanalizing the

more resistant occlusions extending the length of nasolacrimal duct. Such technical factors include flexible, steerable guidewires,[219, 221, 240, 243] hydrophilic-coated wires,[219, 221] nonmetal guidewires,[221] small-caliber catheters 2 to 3 mm in diameter,[221, 243] versus 3 to 4 mm catheters[228] or 4 to 5 mm catheters,[229, 240] decrease or absence of a catheter tip beyond the balloon,[221] shorter inflation period of 20 to 30 seconds,[228] 30 seconds,[221] 1 to 2 minutes,[243] versus 5 minutes,[229, 240] guiding cannulas,[221, 243] a Ritleng probe (through which guidewires may be passed),[224] and canalicular irrigation for flushing out or dislodging possible clots.[220, 221, 240, 245] The reason for consideration of the above factors is the desire to minimize ductal trauma as a factor in recurrence of epiphora, stenosis, or obstruction. Selection of the balloon catheter diameter and timing of inflation should be enough to tear the fibrotic component of the obstruction or stenosis, yet the catheter should be small enough in caliber or the duration of inflation should be short enough to prevent damage to the NLDS. The variety of options suggests that there is no universal solution. Personal preferences and individual choices are noted in the literature.

Strictures of the canaliculi and upper lacrimal sac can restrict the passage of steerable guidewires.[243] The floppy tip of the wire (of flexible systems) may become stuck or may coil in the small lumen of the lacrimal sac and not advance into the nasolacrimal duct. The relatively stiff ball-tip wire,[220] by elevating its handle superiorly, allows ease of manipulation of its tip into the lacrimal sac and the junction with the nasolacrimal duct but is more difficult to pass through stenotic lesions, increasing the risk of ductal wall damage or false passages.[243] Yet such stiff wires may be necessary to advance through the rigidity of complete obstructions of the nasolacrimal duct, where forceful advancement may be required.

Berkefeld et al.,[243] exploring beyond the technical issues in assessing their results in 85 patients treated with balloon DCP, looked at associated clinical factors that may predict reobstruction. They found recurrent episodes of active dacryocystitis; dacryolithiasis filling defects on initial DCG; posttraumatic strictures with bone canal narrowing; or long-segment rigid occlusions of the nasolacrimal duct, all factors in reobstruction, with 89% and 94% 12-month patency rates for focal stenoses or occlusions, respectively, if the above factors were not present. Otherwise, the reobstruction rate was 46% in patients with one of the above factors present.

In patients with active inflammatory changes, the potential benefit from removal of tight stenoses is limited to the short term, with active dacryocystitis involved with restenosis. Similarly, dacryolithiasis was seen to be a common cause of reobstruction after DCP, with filling defects seen on the preliminary DCG felt to be a contraindication to DCP. Posttraumatic stenoses frequently have bony narrowings that are too rigid for balloon dilation, with poor long-term outcomes and secondary inflammatory changes. Patients with multiple or diffuse stenoses or chronic (rigid) occlusions of the entire length of the nasolacrimal duct tend to have early reobstruction, probably secondary to the unavoidable trauma to the ductal wall and reactive mucosal overgrowth.[243] The high recurrence rates, between 45% and 80% in various series,[220, 229, 243] suggest a limited value for balloon DCP. While stent placement may improve technical success rates and midterm patency rates, the long-term implantation of such stents has been associated with recurrence rates as high as 64%, depending on the location of the obstruction.[246] The operative treatment of postsaccal stenosis has consistently shown long-term success rates of 85% to 90%[30, 107–110] for external DCR and at least 75% for endonasal endoscopic DCR.[109] Results are independent of the cause or length of the stenotic lesion, suggesting that DCR, either external or endoscopic in approach, is the preferred approach to these patients with factors suggesting a high rate of reobstruction. For those patients with focal partial obstructions, either junctional (lacrimal sac–nasolacrimal duct) or within the nasolacrimal duct, or with short-distance occlusions of the distal nasolacrimal duct, clinical long-term success with balloon DCP may be realized (80% or more) as a treatment preferable to surgery or stent placement.[243]

Janssen et al.,[221] in noting the varying results of DCP obtained by different authors, felt that the differences may be due to different DCP techniques, as well as patient selection.[239] Lee et al.'s[229] results may have been negatively affected by the inclusion of posttrauma obstruction and possible deformations of the bony lacrimal canal, as well as the inclusion of patients with stenosis of the common canaliculus. Similarly, Ilgit et al.[240] included stenotic common canaliculi in their series. Janssen et al.[221] excluded patients with canalicular stenoses from their series and included patients with posttraumatic obstruction, but only after CT was utilized to evaluate the bony lacrimal canal. Other exclusion criteria included acute dacryocystitis, tumors, sarcoidosis, and Wegener's granulomatosis. No relationship was noted between the duration of epiphora (more or less than 1 year) and initial or long-term success.[221] More interestingly, and in contrast to the findings by Berkefeld et al.,[243] the length of obstruction (short obstruction limited to one level versus obstructions extending to two, three, or four levels) also showed no relationship to initial or long-term success.[221] However, patients with partial obstruction had greater initial and long-term success than patients with complete obstruction.[221] Others also noted these findings.[229, 240, 245]

The mechanism of DCP in the treatment of epiphora due to lacrimal obstruction is relatively unknown. The majority of treated patients have PANDO. As outlined by Linberg and McCormick,[161] the membranous nasolacrimal duct has a loose structure of connective tissue around the stratified columnar epithelium of the lacrimal duct. Within this loose tissue, a venous plexus, lymphocytes, and some fibrous tissue were found. In patients with acquired obstruction, they noted vascular congestion, lymphocytic infiltration, and edema causing compression of the duct, in its earlier phase by active chronic inflammation along the entire length of the narrowed nasolacrimal duct. Such stenosis leads to pooling of tears and infection, which, in turn, increases inflammatory edema and eventually gives rise to fibrosis. At the same time, infection may cause reflex hypersecretion of tears. Janssen et al.[221] postulate that the success of DCP (or DCR) does not necessarily mean long-term patency of the nasolacrimal duct, but rather the breaking of this cycle of obstruction and infection. Balloon dilation may resolve the obstruction but does not remedy the primary inflammatory

Copyright © 2003, Mosby, Inc. All rights reserved.

process, which is likely to affect the recurrence of obstruction, with the dilatation crushing the mucosa of the duct at its stenotic segment, causing the development of a further inflammatory reaction and hemorrhage. Use of topical or systemic anti-inflammatory agents to reduce the early inflammatory reaction, flushing saline with or without antibiotics to dislodge clots, and intubation (or stents) to limit fibrosis and ensure patency have been attempted.

More recently, Kuchar and Steinkogler[247] have performed antegrade dilation of complete postsaccal stenosis patients, assessed by canalicular irrigation and transcanalicular endoscopy, using a Lacricath balloon catheter. Immediate postdilatation irrigation and endoscopy provided evidence of the reopened passage. Silicone intubation, for splinting the reopened stenoses, felt to be important for permanent patency during the initial scarring process, was performed immediately after the dilatation, with the tubes kept in place for 3 to 6 months. Such complementary postdilation silicone intubation, if consistently able to improve long-term patency rates, may offer an alternative to patients currently undergoing stenting. A 1 year patency rate of 73.3% was observed. Antegrade balloon dilatation, in conjunction with transcanalicular endoscopy, was felt to be easy and less expensive, without the need for more expensive imaging equipment the risks of radiation exposure.

The common canaliculus is second only to the lacrimal sac–nasolacrimal junction as the most common site for lacrimal drainage system obstruction.[47] In some patients, for canaliculodacryocystorhinostomy (with partial resection of the canalicular segment), silastic or rubber tubes are surgically placed for several months.[31] The standard surgical treatment of epiphora due to canalicular obstruction is conjunctival DCR, with a permanent bypass tube.[32, 248] Conjunctival DCR, indicated for obstructions at the canalicular level, forms a surgical tract between the conjunctiva and the internal anastomosis of the DCR. Glass (Pyrex) tubes are placed into the conjunctival tract as a permanent prosthesis, bypassing the canalicular obstruction. They require frequent, careful maintenance; may become dislodged or cause mild facial disfigurement; and require frequent cleaning and considerable patient commitment. Recurrent dacryocystitis, granuloma formation, eroded canaliculi, or, rarely, corneal irritation may result from the prolonged placement of such tubes. This surgery, in contrast to the standard DCR involving lacrimal sac or more distal obstructions, is more invasive and leads to a higher rate of recurrence at long-term follow-up. While these oculoplastic procedures have some patient compliance problems, which may suggest DCP as an alternative treatment, experience with DCP[220, 221, 228] suggests that such dilations of the NLDS should be limited to stenosis/obstructions of the distal lacrimal sac and nasolacrimal duct (i.e., the same patients for whom routine DCR is indicated).

Balloon catheter dilation of the canaliculi has been discouraged or considered contraindicated because of possible damage to the canaliculus or punctum.[51, 219, 221, 243] Recurrence rates of up to 60% to 70% were noted.[249] Stenosis in the canaliculi was not considered suitable for balloon dilation, and such dilation was limited to the diameter of the guidewire or lacrimal catheter. The risks of canalicular occlusion caused by laceration or recurrent stenosis seemed high, and operative reconstruction may be difficult in such cases. Those performing DCP must avoid damaging the canaliculi, thereby creating the need for conjunctival DCR and a permanent glass prosthesis that otherwise may not have been necessary.[51]

Other investigators, in small series, reported balloon catheter dilation of the common canaliculus to be safe and effective.[220, 229, 240, 250] These initial series, as well as the surgical limitations of canalicular DCR, have encouraged Ko et al.[251] to develop further their techniques for evaluation of the safety and long-term effectiveness of balloon DCP in the treatment of common canalicular obstruction. In a study of 195 eyes with common canalicular obstruction (84 complete and 111 partial), the authors achieved initial technical success in 90% and 94%, respectively, of these patients. Patency rates were 51% at 6 months, 43% at 1 year, and 40% at 2 years, sparing this group of patients from an operative procedure. Their improved results may be related to the use of a slightly larger 3 mm balloon and better stabilization of the balloon catheter during inflation by passing it further retrograde along the guidewire such that the distal radiopaque marker, instead of the catheter tip, is advanced beyond the punctum, for a more efficient ballooning effect. Technical failures included seven patients with false passages and four patients in whom the obstructed canaliculus could not be negotiated with a guidewire. The recurrence of obstruction seemed related to ductal wall damage from guidewire or balloon catheter manipulation and resultant mucosal overgrowth, fibrosis, and recurrent episodes of active dacryocystitis.[243]

A previously designed polyurethane stent and a technique for lacrimal canalicular obstruction have had only limited experience.[252] The flexibility of the stent led to difficulty in advancing the tapered portion of the stent retrograde through the obstruction from the lacrimal sac. A high rate of stent occlusion occurred secondary to granulation tissue growth into the ballooned-out portion.[252] A more suitable introducer system, as well as a stent with no interstices at the ballooned-out portion, may offer greater success in the nonsurgical treatment of canalicular obstruction.[252]

Stents

The tendency for obstructions to recur after dacryocystoplasty (DCP) may be due to the fibrotic nature of the stenosis/occlusion. Song et al.[238] addressed this problem in patients with obstruction of the nasolacrimal sac or duct with the placement of plastic stents immediately following balloon dilation. The plastic stent, with its distal tip left slightly protruding into the inferior meatus, may be easy to remove. This technique will not interfere with subsequent DCR. The firmness of these stents, however, led to patient discomfort and the need for a softer stent. Metallic stents, initially proposed for the creation of a larger, stable lumen, if blocked after placement, can only be removed surgically and may compromise subsequent DCR.[237, 238] Such metallic stents are also limited by a lack of longitudinal flexibility. Medium-type Palmaz balloon-expandable metallic stents offer greater longitudinal flexibility, with an articulated design for longer stenotic/occluded segments as well as a nonarticulated stent for more focal lesions. Although the

Copyright © 2003, Mosby, Inc. All rights reserved.

balloon and stent could be dilated to 4 mm, stenosis of the stented lumen was noted on follow-up studies.[242] Mucosal-lined tracts do not tolerate metal well.[253, 254] Mucosal hyperplasia and a local inflammatory foreign tissue reaction to the metallic stent by the ductal wall, with tissue ingrowth through the metallic struts, are probable causes of stent stenosis and obstruction. Although tissue ingrowth may stabilize with time, the limited caliber of the NLDS lacks any reserve capacity to tolerate this initial tissue response. Metallic stents in the NLDS have been replaced by softer nonmetallic stents and are no longer used.

Song et al.[230] introduced a soft polyurethane stent that could be positioned with an introducer set (a stent loader, a No. 6 French sheath, a dilator, and a pusher catheter), obviating the need for balloon dilation of a stenotic or occluding segment. This method of DCP has the guidewire placed in an antegrade manner, with the dilator, sheath, and stent positioned in a retrograde fashion (Fig. 10-36,E-H). Fluoroscopic placement of the stent was technically successful in 50 of 51 attempts. Complete resolution of severe epiphora was noted in 47 and partial resolution in 3 of the 50 nasolacrimal systems treated. Treated stenoses were limited to the lacrimal sac, junction, and nasolacrimal duct. During limited follow-up of these patients, no stents migrated. Obstruction of one stent (probably caused by a blood clot) required lacrimal irrigation. It was hoped that this technique, as well as reducing costs, shortening procedure time, and improving patient tolerance, might offer better long-term results.

Song et al.[246] reviewed their long-term patency rate of polyurethane stent placement for the treatment of epiphora in 236 patients (283 obstructed lacrimal systems) with a follow-up period greater than 1 year. Stent placement was technically successful in 270 systems (95%). Assessment of these 270 systems 7 days after stent placement showed 87% with complete resolution of epiphora, 10% with partial resolution, and 3% with no resolution. In 77 patients (29.5%) with initial improvement, recurrence of epiphora occurred at a mean duration of 16 weeks poststenting due to obstruction of the stent. Recurrence rates of stent obstruction were correlated with levels of initial obstruction, with the highest recurrence rates (64%) for obstruction of the lacrimal sac, compared to only 26% for obstruction at the junction of the lacrimal sac–nasolacrimal duct and 15% at the nasolacrimal duct.

The causes of partial resolution of epiphora at 7 days were inadequate placement of the stent or partial obstruction of the stent by blood clot (excluding those patients who also had coexistent common canalicular obstruction). Stent placement was deemed inadequate when its mushroom tip was not placed in the dilated area. In the 3% of patients with no resolution, DCG at 7 days showed patency, and the cause of lack of improvement was not identified. Stent migration was noted in two patients in whom markedly dilated lacrimal systems were noted proximal to the obstruction. The stents were replaced with second stents with wider muchroom tips. Approximately one third of the obstructed stents were able to be recanalized by forceful irrigation with saline through the superior punctum, suggesting that the stents may have been impacted by mucus. Of the 56 obstructed stents removed, mucoid material was found in 26 and granulation tissue in 30. The incidence of mucus plugging within the stent may be managed with acetylcysteine eyedrops[219] or by reinterventions to maintain patency.[246] The growth of granulation tissue into the stents may represent a foreign body reaction[255] and may be overcome by the use of stents without interstices in the ballooned-out portion or a coated drug-releasing stent.[246] Overgrowth of the proximal end of the stent by granulation tissue is a more serious complication.[246] Primary and secondary patency rates after DCP (with balloon dilatation) without stent placement have been higher than those for primary stent placement. In addition to obstruction of the stent, subclinical chronic infection from bacterial overgrowth contributing to a cycle of infection, mucosal swelling, increased obstruction and stasis may result. Rapid restenosis frequently results despite removal of a dysfunctional stent.[239] Total obstruction of the lacrimal sac or common canaliculus may occur, with resultant impossibility of the classic operative DCR. Balloon dilation DCP by itself will not preclude future DCR.

Those patients with epiphora of traumatic etiology had a technical failure rate of 29% (in 34 systems) compared to a 1% technical failure in the larger group of patients with idiopathic epiphora (249 systems) of nontraumatic etiology.[246] Malalignment of the fractured bone is a relative contraindication to nonsurgical placement of a lacrimal stent. The overall patency rates 1 year poststenting of 85% and 74% for stenting of obstructive lesions at the nasolacrimal duct or at the junction between the lacrimal sec and nasolacrimal duct, respectively, are only slightly lower than the patency rates (87%) for DCR.[30, 107–110] Patency rates for stenting obstructive lesions at the contracted lacrimal sac (46%) were considerably lower than those obtained with DCR. Stent placement in the obstructed lacrimal system is most valuable as initial therapy for obstructions below the junction between the lacrimal sac and the nasolacrimal duct.

Berkefeld et al.[243] have expressed reservations about implantation of plastic prostheses (stents) for predominantly benign stenoses of a small-caliber, slow-flow ductal system. Complications may render operative reconstruction difficult. The authors suggest operative treatment for those patients not suitable for balloon DCP. Although placement of stents in the NLDS offers interesting possibilities for duct patency, chronic infection and fibrotic reactions may occur in the end, suggesting that the number of patients who receive a stent as initial treatment of lacrimal system obstruction and the indications for stent placement should be reconsidered.[221]

Assessment of the NLDS prior to placement of a stent may help prevent stent failure. A small, fibrotic lacrimal sac that does not have the capacity to receive the expanded mushroom tip will allow the stent to migrate and occlude. The size of the sac should allow proper placement of the stent below the internal punctum (sinus of Maier) with complete expansion of the mushroom tip. If the head of the stent is placed high in the sac, the stent may contact and block the internal punctum, blocking tear drainage and causing common canaliculus obstruction.[238] Accumulation of tears under the head of the stent may predispose the lacrimal sac to infection.[244] An incorrect length of the stent, with the distal tip contacting the nasal floor, may also lead to poor drainage. False passages are occasionally created, usually with the stent noted to be too medial in position,

passing through the very thin bone of the medial wall of the inferior lacrimal sac fossa, during attempts to probe or pass the guidewire or stent through very tight obstructions. More recently, increased reporting of false passages during stent placement, either by the guidewire or by the stent, has been noted.[154, 156, 244] A site of relative weakness at the inferior medial aspect of the lacrimal sac, where Horner's muscle is incomplete or deficient, compared to the muscular envelope noted surrounding the remainder of the sac, was inferred to be a common site in four of five perforations.[154] The assistance of CT imaging, either routinely or if there is any concern about positioning of a guidewire or stent, during or after the procedure, may help identify malpositioned components.[154, 256]

Pabón et al.[256] noted that placement of the stent, confirmed in the proper anatomic tract, was a critical factor affecting long-term patency, with 73% of 61 such stents patent at 1 year compared to none of the 7 improperly positioned stents. Early stent blockage and the need for periodic irrigation may be indicative of malpositioning of the stent.

The presence of epiphora reflects abnormal drainage. The increased number of treatment options (probing, irrigation, intubation, external dacryocystorhinostomy (DCR), endocanalicular DCR, endoscopic DCR, dacryocystoplasty, stent placement) for the epiphora patient have led to a desire for increased functional and anatomic data from various imaging modalities to assist treatment decisions based on the site and nature of the obstruction or stenosis. For nasolacrimal duct obstruction, it is important to differentiate functional (incomplete or partial) from mechanical (complete) obstruction. If the stenosis is mild or incomplete and obstruction can be overcome during a pressure injection, then DCP or stent placement may be considered instead of DCR.[227] More static images, such as those obtained with CT-DCG or MR-DCG (especially if teardrop placement of contrast is used) or radiographic distention-DCG may not offer the required functional information.[227]

The role of CT-DCG immediately following DCG (with residual contrast in place) may assist patient selection for DCP for patients with posttraumatic obstruction,[189] patients with previous DCR failure,[194] or those in whom the guidewire cannot be passed with ease during DCP.[221] At the time of DCG, if imaging findings were suggestive of dacryocystitis, posttraumatic obstruction of the bony canal, tumors, sarcoidosis or Wegener's granulomatosis, these patients received CT for further assessment and possible exclusion from DCP consideration.[221] CT assessment of the nasolacrimal bony canal may reveal minimal diameters ranging from 2.5 to 4.0 mm,[221] in contrast to the assumed canal dimensions of 4 to 6 mm previously described.[158, 163]

Hurwitz[30] has outlined indications for DCR, including epiphora due to acquired obstruction within the nasolacrimal sac and duct; mucocele of the lacrimal sac; chronic dacryocystitis or conjunctivitis due to lacrimal sac obstruction; lacrimal sac infection that must be relieved before intraocular surgery; and congenital nasolacrimal duct obstruction that cannot be cured by probing. As noted by the recent number of articles on DCP or stenting,[246, 218, 221, 240] these are the same indications considered appropriate for DCP or stenting. Attempts to refine DCP techniques and patient selection criteria, as well as controlled studies, may better define which procedure is best suited for specific patients. More stringent definitions of success, including minimum 2 year follow-up, resolution of the patient's presenting complaint, and 100% patency on syringing tests, would allow more appropriate evaluation of comparative treatments (J.J. Hurwitz, personal communication). DCR remains the treatment of choice for patients with posttraumatic or congenital obstruction of the bony nasolacrimal canal or obstruction of the nasolacrimal canal due to polyps or granuloma. Contraindications to DCR—acute dacryocystitis and tumors of the lacrimal sac,[30]—are also contraindications for dacryocystoplasty.[221]

ENDOSCOPY OF THE LACRIMAL DRAINAGE SYSTEM

A prototype of a lacrimal canaliculoscope, develops in 1990, passed nicely into the canalicular system, was rigid, was less than 1 mm in external diameter—equivalent to a No. 0 lacrimal probe—and allowed direct visualization of the punctum and canaliculus.[257, 258] Newer-generation flexible endoscopes measure 0.3 to 0.5 mm in diameter and have good axial illumination and a 70° field of view, allowing direct visualization and excellent images of the canaliculi, lacrimal sac, nasolacrimal duct, and their mucous membranes[259] (Fig. 10-37). The endoscopic unit includes a Xenon light source, a video camera with an ocular attachment and a miniature camera system with a monitor and video camera. The above system can be combined with modified Jünemann probes, which have attachments for endoscopy and irrigation. Some probe models have a third attachment to couple a laser fiber.

Such procedures are performed in an outpatient setting with topical anaesthesia and a pericanalicular and perisaccal local anaesthetic. The punctum is dilated, and the endoscope is inserted and advanced during steady, gentle irrigation, which is necessary for good visibility. Patients experience discomfort similar to that of standard probing and irrigation.[259] Normal distention of the lacrimal system is seen as widening of the lumen and easy passage of the endoscope. Stenoses cannot be widened during irrigation and the endoscope meets with a degree of resistance, as in conventional probing. Mucosal characteristics can be identified and correlated with the type of obstruction. Normal lacrimal mucosa is smooth and pink; postinflammatory conditions show thickened reddish-gray mucosa with large papillae; stenosis (fibrotic plaque) presents as whitish-gray inelastic membranes; and submucosal folds are seen as thick gray strictures.[259] Heavy debris and secretions may be differentiated from complete stenosis by their clearance with irrigation. Partial obstruction may be visualized as a narrowed lumen, which widens during irrigation. Difficulties have been noted initially in the handling of the instruments, evaluation of the mucous membranes, or diagnosis of pathologic changes. There is improvement with experience and recognition of landmarks.[259] Endoscopy is currently utilized to visualize directly and localize more precisely obstructing lesions of the NLDS. Endoscopic examinations, combined with various types of lasers, may be utilized for treatment (endocanalicular laser-assisted DCR).

However, to date, bone penetration and osteotomy formation have been less successful than for external DCR.[39]

SUMMARY

Epiphora is a common ophthalmologic complaint for which a number of imaging modalities are available. In our hands, intrinsic etiologies, based within or limited to the luminal component of the NLDS, remain routinely best assessed by digital subtraction (DS-DCG), with real-time images detailing the fine anatomic structures of the NLDS, including stenoses, obstructions (partial or complete), calculi, or morphologic abnormalities such as diverticulae or fistulae. CT and MR imaging display extrinsic lesions affecting the NLDS or mass lesions of the medial canthal and sinonasal-orbital regions. Without a proper index of suspicion, the lack of specificity of clinical signs in the epiphora patient may mask the opportunity to assess causal conditions arising within the wall, extramurally, extraorbitally, within the adjacent paranasal sinuses or nasal cavity. CT offers the advantage of better overall assessment of both bone and soft-tissue detail and tends to be used more frequently, when craniofacial information is desired, as in face trauma or involvement by tumor of the adjacent bone structures. MR imaging offers excellent soft-tissue resolution, especially with orbital surface coils. To better visualize the NLDS on CT or MR imaging, these studies may be complemented by cannulation, with administration of DCG contrast medium, or contrast may be placed topically into the conjunctival cul-de-sac, as a less invasive test that may offer limited functional information. Specific MR-DCG techniques, to highlight fluids (e.g., water, saline) introduced within the NLDS, as a noncontrast medium-detectable substance, show promise but currently do not offer the anatomic detail seen with DS-DCG or the functional analysis seen with DSG. DSG remains an excellent modality for assessing the dynamics of the NLDS, including canalicular dynamics and the lacrimal pump, functional obstruction, and delays in transit. Data analysis and

time-activity curves remain an important component of the study offering a quantitative picture of lacrimal drainage, and are especially useful in assessing those epiphora patients with no abnormality seen on DCG.

DCR remains the most consistent surgical treatment for epiphora secondary to an obstruction of the NLDS, with success rates approaching 90%. An alternative treatment, balloon DCP, is a less invasive, simple procedure performed under local anaesthetic on an outpatient basis. With careful patient selection, the most experienced clinicians have achieved encouraging results, approaching those for DCR. Stent placement may yet have a role, but it is no longer suggested as a primary alternative treatment. Knowledge of the criteria for patient selection for surgical procedures (external versus endoscopic DCR) or the alternative treatment, DCP, has led to greater awareness of NLDS factors and a more detailed analysis of lacrimal drainage imaging studies. Lacrimal endoscopy offers direct visualization of the NLDS membranes and precise localization of obstructing lesions. There is a learning curve. The exact role of lacrimal endoscopy, either as a diagnostic tool or in conjunction with surgical approaches such as laser DCR, has yet to be defined.

Acknowledgments

The authors wish to express their appreciation to Chris Bobkowski and Salvatore Ceniti for their assistance in the preparation of this manuscript and to Jeff Hurwitz, MD. The authors acknowledge the close working relationship between the Departments of Ophthalmology and Medical Imaging and the stimulation of the radiologists' interest in the pathology of the NLDS by their clinical colleagues.

The retrobulbar visual pathway (Fig. 11-1) includes all neural pathways involved in visual function from the point where the optic nerve originates in the posterior globe to the primary visual cortex lying within the medial aspects of the occipital lobes. The elements of the pathway can be affected by a variety of pathologic conditions, which, depending on their location, give rise to characteristic clusters of clinical symptomatology. The apparent symptoms therefore enable

VIEW IMAGE

the pathologic condition to be localized along the visual pathway with a high degree of certainty. For this reason, imaging techniques may be tailored to display the expected condition optimally. In the past, these imaging techniques included plain radiographs, orbital venography, pneumoencephalography, and complex motion tomography. However, during the past two decades, computed tomography (CT) and magnetic resonance (MR) imaging have become the mainstays of visual pathway imaging because they allow direct visualization of the elements of the pathway and the pathologic processes contained therein. Today, MR imaging is the procedure of choice.

This chapter defines the anatomy of the visual pathway, discusses the relevant embryology, delineates the role of CT and MR imaging, discusses the various pathologic entities that can affect the visual pathway and their clinical symptomatology, and illustrates the appearance of these pathologic conditions.

EMBRYOLOGY OF THE RETROCHIASMATIC VISUAL PATHWAY

Embryologic development of the retrochiasmatic visual pathway is a complex process that occurs in a sequential, stepwise fashion. It involves the growth and development of both neural and vascular structures and is also affected by influences stemming from developing osseous structures.[1, 2] The embryology of the globe (discussed in Chapter 8) and optic nerve is described in general terms to place the development of the retrochiasmatic structures in perspective.

During the embryonic period of fetal life, specifically at 4 weeks of gestation, early vesicularization of the developing brain occurs.[1, 2] The optic pits appear on the surface of the rostral end of the developing embryo, and shortly thereafter, the optic vesicles evaginate from the prosencephalon, and the lens placode begins developing within the optic vesicle. By the end of 5 weeks of gestation, the optic vesicle has invaginated, forming the optic cup and the fetal fissure, a crease in the surface of the optic cup and stalk in which the hyaloid artery travels to vascularize the lens of the vesicle. Subsequently, early development of the various layers of the retina occurs. Within the developing retina, the axons of the ganglion cells begin to project into the optic stalk, giving rise to the first discernible structure of the optic nerve. By the end of 6 weeks of gestation, the lens capsule has formed around the lens vesicle, and progressive closure of the fetal fissure has begun.

The anlagen of the extraocular muscles begin to develop, arising from mesodermal tissues of the orbit, and by the end of 7 weeks of gestation, the fetal fissure has completely closed. At this time, the axons of the ganglion cells forming the optic nerve fibers reach the most proximal end of the optic stalk, with some crossing to form the chiasm. The lateral geniculate bodies begin to appear. The meningeal sheath surrounding the optic nerve forms and is contiguous with the dura covering the brain, as well as with the sclera enclosing the globe. Rods and cones begin to develop as a result of further retinal differentiation, and by the end of 8 weeks of gestation, retinal differentiation has progressed rapidly and the bony orbit has begun to develop. The optic stalk is entirely filled with nerve fibers, and as a result, the cavity of the optic vesicle no longer communicates with that of the forebrain. The optic chiasm is fully formed and separated from the floor of the third ventricle, with only the optic recess remaining as a remnant of the optic vesicle.

In the fetal period of intrauterine development, the optic pathway develops further, especially within the more central portions.[1, 2] By the end of 9 weeks of gestation, early differentiation of the occipital cortex is noted. At this point, the retina demonstrates a more mature, layered appearance, and by the end of 10 weeks of gestation, the optic tract has fully formed. The axons forming the optic nerve and tract reach the lateral geniculate bodies in the dorsolateral part of the mantle layer of the thalamus, and differentiation of the occipital cortex into marginal and mantle layers is completed by the end of 11 weeks of gestation, with full

Copyright © 2003, Mosby, Inc. All rights reserved.

elaboration of the peripheral cortical layer. By the end of 16 weeks of gestation, the adult form of retinal vascularization is seen with entry of the central retinal artery via the optic nerve head, resulting from progressive atrophy of the hyaloid system.

Myelination of the optic tracts begins at the lateral geniculate nuclei at 20 weeks of gestation and proceeds peripherally in a direction opposite to that of axonal growth. The choroid now demonstrates three distinct layers. Myelination of the optic tract and chiasm continues from 24 to 28 weeks of gestation, and progressive enfolding of the calcarine cortex forming the calcarine fissure is noted. By the end of 32 weeks of gestation, all layers of the retina have been entirely formed, and the eyelids, which previously were fused, are now unfused. By the end of 36 weeks of gestation, the optic nerve has completed its myelination to the lamina cribrosa. Myelination of the optic radiations does not begin until approximately the time of birth. It then proceeds centrifugally over a 4-month period, beginning from the calcarine cortex toward the lateral geniculate bodies.

ANATOMY OF THE VISUAL PATHWAYS

Light enters the globe via the cornea, passes through the aqueous humor, lens, and vitreous humor, and then strikes the retina, impinging on photoreceptor cells in the most posterior layer of its laminated structure. Depolarizations occur within the rods and cones, which transmit impulses to the bipolar cells in the intermediate layer of the retina. These bipolar cells are the primary afferent neurons of the visual system. Impulses are then transmitted to the ganglion cells, which lie in the more superficial anterior layer of the retina. The axons of the ganglion cells course upon the most anterior surface of the retina, converging on the posterior pole of the eye, where they initiate a 90° turn and pierce the sclera at the lamina cribrosa, coalescing to form the optic nerve. Myelination of the axons of the optic nerve occurs only within those axons that are outside the globe.[1] The axons anterior to the lamina cribrosa are not myelinated.

The optic nerves pass dorsomedially to the orbital apex, entering the skull via the optic canals.[3] They then combine at the optic chiasm, which is superior to the sella turcica in the suprasellar cistern at the base of the brain. Axons from the nasal half of the retina decussate to contribute to the contralateral optic tract, whereas axons from the temporal half of the retina remain uncrossed.

Each visual field projects on parts of both retinas, with the right visual field projected on the nasal half of the right retina and the temporal half of the left retina. A monocular crescent of the most peripheral area of the right visual field is projected only onto the nasal half of the right retina because of anatomic asymmetry, with the nasal retina being longer than the temporal retina. Fibers from both retinas, which carry information about the right visual field, combine at the optic chiasm, forming the left optic tract. Therefore the whole right visual field projects to the left hemisphere.[1]

The optic tract courses dorsolaterally around the hypothalamus and the rostral part of the cerebral peduncle within the perimesencephalic cistern, synapsing with cells of the lateral geniculate bodies (Fig. 11-1). A small number of fibers, the pupillary motor fibers, project in a medial caudal direction, forming the brachium of the superior colliculus, a projection to the superior colliculus and pretectal areas. The lateral geniculate nucleus lies in the dorsolateral aspect of the thalamus, ventral to the pulvinar and lateral to the medial geniculate body and cerebral peduncle. It is a precisely ordered six-layered structure. The contralateral half of the binocular visual field is represented in all layers of the lateral geniculate body. However, crossed and uncrossed fibers end in different layers. Crossed fibers project to layers 1, 4, and 6, whereas uncrossed fibers project to layers 2, 3, and 5.

Cell bodies of the lateral geniculate nucleus give rise to the optic radiations (geniculocalcarian tracts), which pass to the ipsilateral primary visual cortex lying on the medial aspect of the occipital lobes surrounding the calcarian sulcus (Fig. 11-1). Fibers of the optic radiations first pass through the retrolenticular part of the internal capsule (the most posterior part of the posterior limb of the internal capsule). They then arch laterally around the lateral ventricles and sweep posteromedially to synapse with cell bodies in the calcarine cortex. Fibers from the ventrolateral aspect of the lateral geniculate nucleus, carrying information from the inferior quadrant of the retina (superior visual field), sweep ventrally into the temporal lobe, pass laterally over the inferior horn of the lateral ventricle forming the so-called Myer's loop, and turn posteriorly to proceed to the calcarine cortex, inferior to the calcarine sulcus. Fibers from the dorsomedial aspect of the lateral geniculate nucleus, carrying information from the superior quadrant of the retina (inferior visual field), follow a more direct posterior course to the calcarine cortex, superior to the calcarine sulcus.

The calcarine cortex is topographically ordered in an anterior to posterior direction, as well as in a superior to inferior one.[1] The most posterior area receives information from the central (macular) visual field, the middle third receives binocular information from the contralateral visual field, and the most anterior third receives monocular information from the contralateral visual field. From the cell bodies lying within the calcarine cortex, axons project to the visual association cortex in surrounding areas.

As a result of precise topographic localization of the visual fields at each part of the visual pathway, discrete lesions can be localized clinically with a high degree of accuracy. Lesions causing interruption of the optic nerve result in monocular blindness (Fig. 11-2). Lesions interrupting the decussating fibers at the optic chiasm cause bitemporal hemianopsia (Fig. 11-3). Partial interruption of the retrochiasmal portion of the visual pathway results in incomplete hemianopsias that are localizing. With complete interruption and total homonymous hemianopsia, there is no localizing information. Interruption of the pathway at the optic tract causes contralateral homonymous hemianopsia. If the optic radiations are interrupted within the temporal lobe, a contralateral superior quadrantanopsia results (Fig. 11-4). Cortical lesions (Fig. 11-5) superior to the calcarine sulcus result in an inferior quadrantanopsia, whereas lesions inferior to the calcarine sulcus (Fig. 11-6) cause a superior quadrantanopsia. Lesions of the occipital pole result in central macular hemianopic deficits.

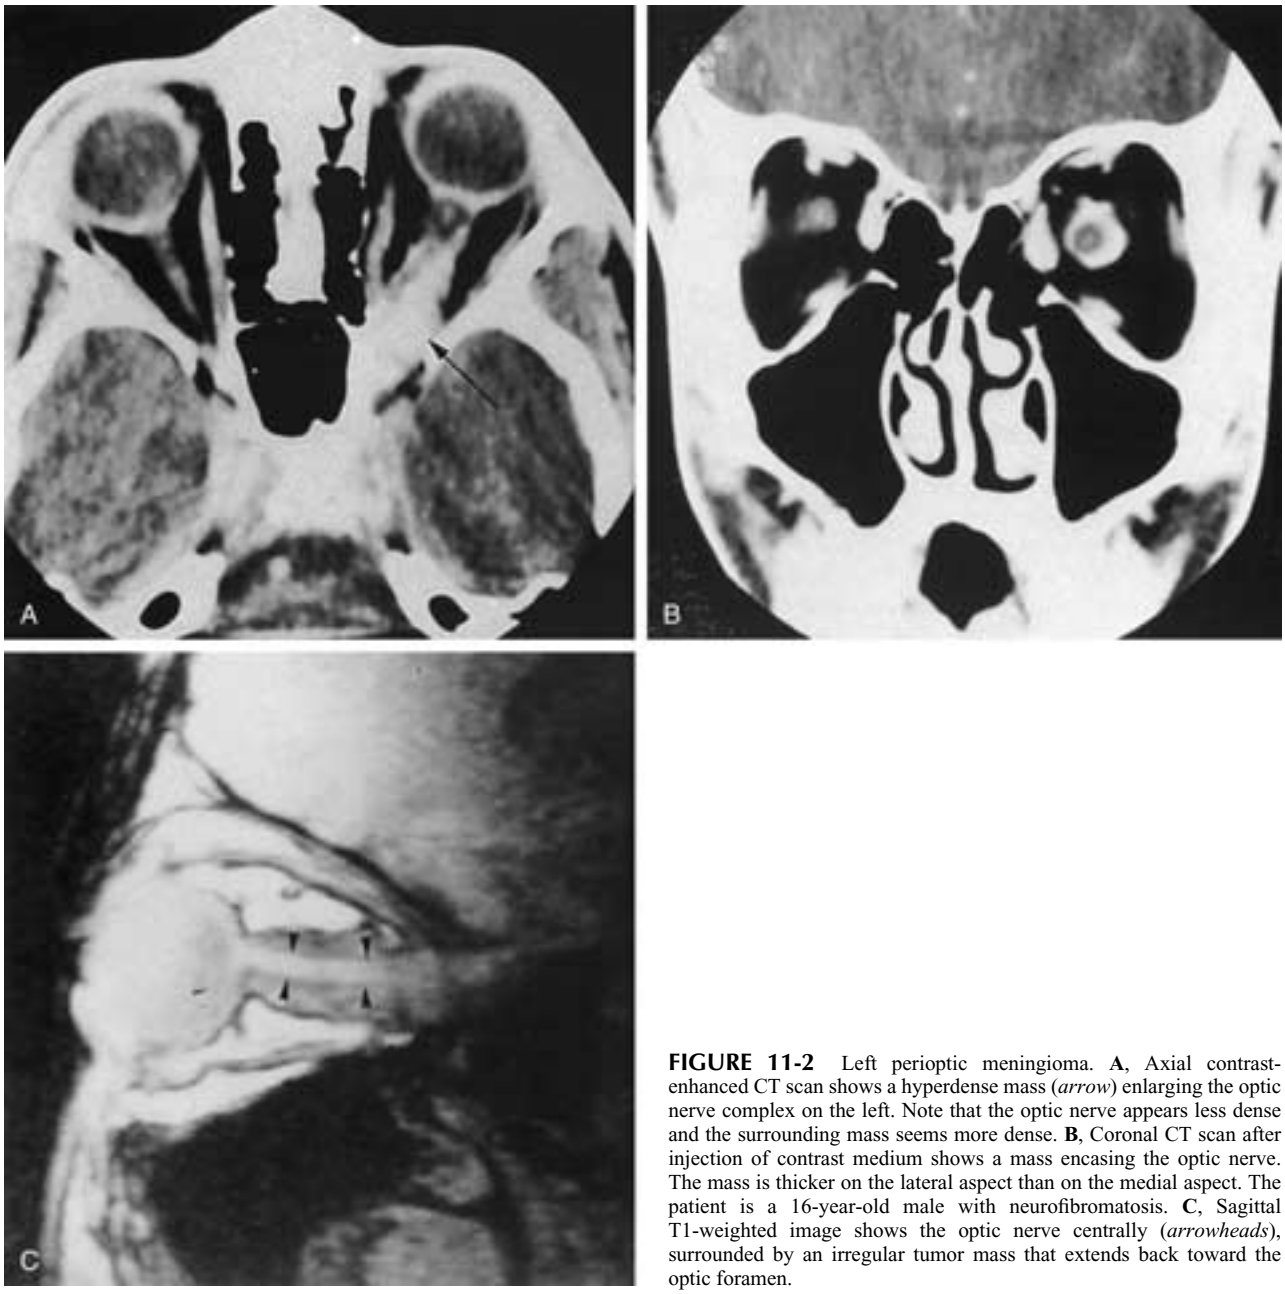

FIGURE 11-2 Left perioptic meningioma. **A**, Axial contrast-enhanced CT scan shows a hyperdense mass (*arrow*) enlarging the optic nerve complex on the left. Note that the optic nerve appears less dense and the surrounding mass seems more dense. **B**, Coronal CT scan after injection of contrast medium shows a mass encasing the optic nerve. The mass is thicker on the lateral aspect than on the medial aspect. The patient is a 16-year-old male with neurofibromatosis. **C**, Sagittal T1-weighted image shows the optic nerve centrally (*arrowheads*), surrounded by an irregular tumor mass that extends back toward the optic foramen.

VIEW IMAGE

IMAGING TECHNIQUES

The indications for imaging of the optic pathways are based on clinical findings and symptomatology, which include some form of visual loss. The rapidity of onset of visual loss suggests the type of pathologic condition responsible, whereas the specific visual field deficit suggests the location of the pathologic process within the visual pathway. In a patient under 45 years of age, sudden onset of monocular blindness, when associated with pain, suggests an optic nerve neuritis. Gradually progressive monocular blindness, especially if associated with proptosis, suggests a mass lesion such as perioptic meningioma involving the optic nerve sheath (Fig. 11-2) as one of the likely causes. The ophthalmoscopic findings of disk edema or optic atrophy are frequently associated with neoplasia and mass effect or an inflammatory process. If the finding is unilateral, the optic nerve is the likely site of involvement. However, if bilateral disk edema or optic atrophy is present, an intracranial cause is more likely. For example, papilledema is bilateral disk swelling due to increased intracranial pressure. Bitemporal hemianopsia is most commonly caused by a disease involving the optic chiasm; the most common disease is a pituitary adenoma (Fig. 11-3) that causes compression of the decussating fibers of the optic pathway. Other conditions with similar clinical findings include lesions that cause extrinsic compression of the chiasm (e.g., craniopharyngioma, meningioma, or carotid artery aneurysm) or intrinsic lesions of the chiasm, such as a chiasmatic glioma. Inflammatory conditions such as sarcoidosis, Langerhans' histiocytosis X, or tuberculosis may also involve the optic chiasm. Homonymous hemianopsia suggests a disease

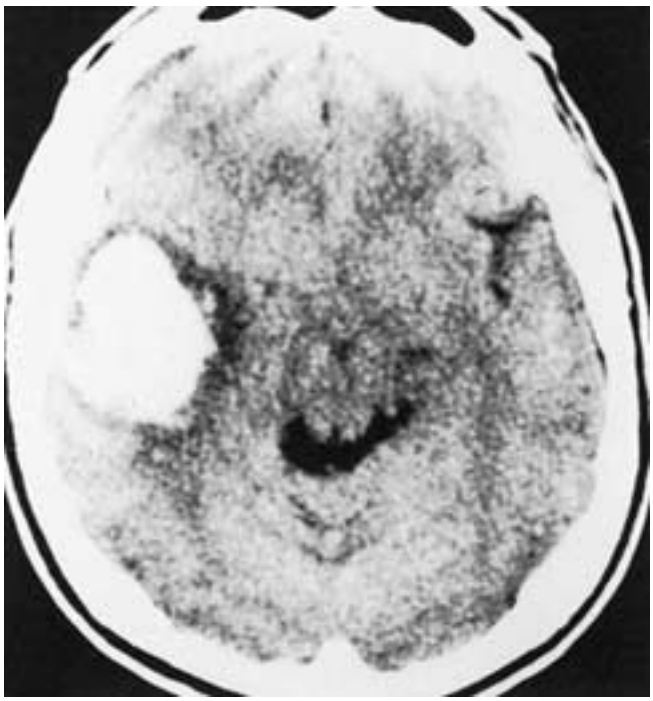
process involving the retrochiasmatic portion of the visual pathway. Sudden onset of this visual field deficit suggests a vascular cause, whereas more gradual development suggests a mass lesion as the cause. If the deficit is incomplete and congruent (equally involving the superior and inferior quadrants of the contralateral visual field), the lesion is likely to lie within the calcarine cortex of the occipital lobe (Fig. 11-5). If the deficit is incomplete and incongruous, the lesion is likely to involve optic tracts, or it may lie either in the temporal lobe involving Meyer's loop (superior quadrantinopsia) (Fig. 11-4) or in the parietal lobe (inferior quadrantinopsia) (Fig. 11-7).



VIEW IMAGE

FIGURE 11-4 Temporal lobe hematoma. Axial CT image shows a hyperdense mass in the anterior aspect of the right temporal lobe.

CT evaluation of the visual pathway should be obtained with intravenous contrast enhancement unless the patient has experienced recent trauma or has a history of severe contrast reaction, or unless a foreign body, hemorrhage, or infarction along the course of the visual pathway is suspected. Axially oriented 5-mm-thick, contiguous CT sections should be obtained from the foramen magnum to the orbital floor; then 2-mm-thick sections should be obtained from the orbital floor to the orbital roof.[4] The remainder of the head can be imaged with contiguous 5-mm-thick scans. Coronal contiguous images 2 mm thick should be obtained with the patient's neck in maximally tolerated extension. The anatomic region included should extend from the dorsum of the sella to the anterior aspect of the globe and should include the sella turcica and the orbit.[5] A 20-cm field of view should be used for the axial images, with subsequent magnification of the orbital region to maximally display any pathology in the area. The coronal images should be obtained with a 12- to 15-cm field of view.

In general, MR imaging is the modality of choice for visualization of the elements of the visual pathway, except in patients with a history of trauma or when a fracture or foreign body with unknown ferromagnetic properties is suspected.[6–9] Once a modality for imaging has been chosen, the imaging protocol may be specifically altered to visualize optimally the region of the optic pathway most likely to contain the pathologic condition.

MR imaging of the elements of the optic pathway involves the use of a head coil. A dedicated orbit surface coil can be utilized to evaluate intraorbital lesions. Using the head coil, axial and coronal images with a TR of 500 to 800 msec and a TE of 20 msec should be obtained. Scans 3 mm thick, with no interscan space, one excitation, a 256 × 256 matrix, and a 14-cm field of view optimally display the structures of the orbit.[6, 10] The remainder of the intracranial optic pathway may be imaged using a sagittal TR 600, TE 20 spin-echo sequence with 5-mm-thick images, a 22-cm field of view, two excitations, and a 256 × 256 matrix. This should be followed by an axial study using a TR of 6000 and a TE of 100 msec, 5-mm-thick slices, one or two excitations,

a 512 × 512 matrix, and a 20-cm field of view.[8, 11] Techniques designed to suppress the signal from the orbital fat make pathologic conditions involving the optic nerve more visible and may be useful when subtle lesions are suspected.[12, 13] One such sequence involves the use of inversion recovery imaging (STIR).[14] Such a technique uses a TR of 2500, a TE of between 30 and 60, a TI of 150, two excitations, a 256 × 256 matrix, 3-mm-thick images, and a 1-mm interscan space. Fat suppressed, T2-weighted spin-echo images with a 256 × 256 matrix and a 2-mm slice thickness in the axial and coronal planes are also useful. In fluid attenuated inversion recovery imaging (FLAIR) the high signal of cerebrospinal fluid (CSF) is suppressed, while showing the abnormal high signal of increased water in pathologic tissue such as plaques of multiple sclerosis or areas of acute infarction.[15] FLAIR imaging can be obtained with turbo sequences in 3 minutes with a 256 × 256 matrix, one acquisition, and a 5-mm slice thickness. A typical pulse sequence uses a TR of 9000 msec, a TE of 120 msec, and a TI of 2200 msec. Contrast enhancement achieved with intravenous administration of gadolinium diethylenetriaminepentaacetic acid (DTPA) in a dose of 1 mmol/kg has demonstrated clinical utility in diagnosing both intraorbital and intracranial pathologic conditions, including neoplasms and inflammatory or infectious conditions. The use of fat-saturated, T1-weighted images with gadolinium enhancement in the axial (Fig. 11-8) and coronal (Fig. 11-9) planes is currently the procedure of choice for detecting abnormal enhancement of the optic nerve or surrounding tissues.

NORMAL CT AND MR IMAGING ANATOMY

The normal intraorbital optic nerve/sheath complex is well visualized on axial and coronal CT because of the natural contrast between it and the surrounding retrobulbar adipose tissue.[14] The normal optic nerves appear symmetric and homogeneous. The normal diameter of the nerve is 3 to 5 mm (average, 4.5 mm) on axial scans and 4 to 6 mm (average, 5 mm) on coronal scans.[4, 16] The intracanalicular portion of the optic nerve is poorly visualized with CT because of beam-hardening artifact from the surrounding bony canal. Unless intrathecal contrast material is used,[5, 17] the intracranial portion of the nerve, as well as the optic chiasm and optic tract, are poorly visualized on CT because of inadequate contrast between the CSF and the neural tissues.[5] Without contrast material in the CSF, the location of the intracranial portion of the nerve, the optic chiasm, and the optic tract is inferred on the basis of knowledge of their anatomic location relative to adjacent structures such as the suprasellar cistern, hypothalamus, medial aspect of the temporal lobes, and lateral aspect of the midbrain. The position of the lateral geniculate nucleus (LGN) is inferred by localizing the pulvinar of the thalamus, since the LGN is

Copyright © 2003, Mosby, Inc. All rights reserved.

not directly visualized on CT. The optic radiations also are not directly seen, but their expected location may be inferred by observing the appropriate area of the temporal lobe adjacent to the temporal horn of the lateral ventricle and the parietal lobe adjacent to the atrium of the lateral ventricle. The most distal portion of the optic radiation can also be inferred by its position relative to the occipital horns of the lateral ventricles. The calcarine cortex is directly visualized along the medial aspect of the occipital lobes.

On MR imaging, using spin-echo short TR/TE (600/20) and long TR/short TE (3000/30) sequences, the intraorbital optic nerve demonstrates signal intensity similar to that of cerebral white matter.[5] It is of low signal intensity relative to the high signal intensity of the retrobulbar adipose tissue. On spin-echo long TR/long TE (3000/90) images, the optic nerve has a signal intensity similar to that of orbital fat; however, often a small amount of high signal intensity CSF can be visualized in the subarachnoid space between the nerve sheath and the optic nerve. On turbo spin-echo long TR/long TE (6000/1000) images, the high signal intensity CSF outlines the optic nerve. The intracanalicular portion of the optic nerve is well visualized on MR imaging because of the absence of signal from the cortical bone forming the optic canal.[6] Short TR/short TE imaging sequences, particularly in the coronal projection, display the intracranial portion of the optic nerve as a relatively higher signal intensity structure within the lower signal intensity CSF of the suprasellar cistern.[18] The optic chiasm and optic tracts demonstrate similar characteristics and are best visualized in either the coronal or sagittal plane.[19] The LGN occasionally may be seen on long TR/long TE images as a high signal intensity nuclear aggregation. More commonly, the LGN is seen as a contour arising from the diencephalon and protruding into the ambiens cistern adjacent to the thalamus. The optic radiation may be seen as cerebral white matter intensity structures within the temporoparietal and occipital lobes; their course is inferred by knowledge of the anatomic location of this portion of the optic pathway. The calcarine cortex may be directly observed on either coronal, axial, or sagittal short or long TR images. The two gyri making up the primary visual cortex may be positively identified, since they are easily seen flanking the calcarine sulcus.

PATHOLOGIC CONDITIONS

Optic Nerve Visual Pathway Glioma

Gliomas of the optic nerve or visual pathway are relatively uncommon low-grade neoplasms that can involve various portions of the retrobulbar visual pathway, including the optic nerve, chiasm, optic tracts, and radiations. These tumors appear most frequently during the first decade of life, and there is a slight female preponderance. There is also an association between optic nerve gliomas and intracranial visual pathway gliomas and neurofibromatosis type 1.

Clinical Findings

Optic nerve gliomas constitute approximately 3% of all orbital tumors; they outnumber perioptic meningiomas by approximately 4 to 1.[10] Optic nerve gliomas occur most frequently in the first decade of life (median age, 5 years); however, they may be present at birth and have been reported in patients as old as 60 years of age.[20, 21] They may occur at any point in the retrobulbar visual pathway, including the optic nerve, chiasm, or optic tract, lateral geniculate bodies, and optic radiations.[20–22] Involvement of the optic chiasm coexistent with gliomas of both optic nerves is more common than involvement of a single optic nerve.[20] Bilateral optic nerve gliomas imply neurofibromatosis type 1. Invasion of the globe by the tumor, although extremely rare, has been observed.[21]

Approximately 15% or more of patients with optic nerve gliomas demonstrate the findings of neurofibromatosis at the time of diagnosis (range, 12% to 38%).[20, 21] Visual pathway gliomas appear early in life, often before the clinical stigmata of neurofibromatosis become evident.

The clinical picture of patients with optic nerve gliomas depends on whether the primary involvement is orbital or intracranial. Intraorbital gliomas usually appear early, with

Copyright © 2003, Mosby, Inc. All rights reserved.

painless proptosis. Globe motility usually is not restricted. Optic atrophy is the most frequent ophthalmoscopic finding, with occasional disc edema.[20] Loss of or decreased vision occurs and may progress to total loss of vision. Occasionally, peripheral visual constriction may be observed. Clinically, intraobital optic nerve glioma and meningioma are difficult to differentiate.[21]

Intracranial visual pathway gliomas generally appear with symptoms related to the portion of the brain that is involved. These symptoms include seizures, nystagmus, hydrocephalus, and changes in mental status. Loss of vision is the most common initial symptom.[20] The presence of nystagmus is highly suspicious for chiasmal involvement.

Pathologic Findings

The cell of origin for optic nerve gliomas has not been definitively elucidated; thus, these neoplasms are included in the general classification as gliomas. Specifically, they are usually classified as grade I astrocytomas (juvenile pilocytic astrocytomas).[20, 22] The tumors are slow-growing, with no tendency to metastasize. Malignant transformation does not occur in childhood gliomas. Development of optic nerve gliomas is observed to occur in stages, from generalized hyperplasia of the glial cells within the nerve to complete disorganization with loss of landmarks within the nerve and the nerve sheath. The tumor usually causes smooth fusiform enlargement of the optic nerve (Fig. 11-10), although it may be somewhat asymmetric with respect to the nerve. A reactive meningeal hyperplasia may be incited, which extends beyond the position of the tumor itself, making it difficult to differentiate it from a perioptic meningioma.[22] Microscopically, the tumor is composed of round, spindle-shaped cells similar in appearance to those of the normal optic nerve. Because no mitoses are present, the tumors do not enlarge by cell division, but rather by hyperplasia of adjacent glial connective tissue and meninges, with

FIGURE 11-10 Neurofibromatosis type 1. Newly diagnosed optic nerve gliomas at age 15 months. The patient had recent onset of proptosis on the right. **A**, Axial T2-weighted image (TR 6000/TE 99) shows proptosis and expansion of the right optic nerve and flattening of the optic nerve head. **B**, Axial T1-weighted image with fat saturation (TR 650/TE 12/3 mm) shows diffuse enhancement of the right optic nerve glioma from the intracranial through the intracanicular to the intraorbital portion. There is faint enhancement of the intracranial portion of the left optic nerve. **C**, Postenhancement sagittal T1-weighted image with fat saturation image (TR 779/TE 12; 3-mm section) shows expansion and enhancement of the intracranial optic nerve just proximal to the optic canal. The chiasm is uninvolved.

production of intracellular and extracellular mucopolysaccharides.

CT Appearance

Optic nerve gliomas may be unilateral or bilateral.[23] Unenhanced CT of these tumors typically demonstrates a marked diffuse, often fusiform, enlargement of an optic nerve, often with a characteristic kinking or buckling.[21, 24] Within the tumor, areas of lucency caused by mucinous or cystic changes may be observed, but calcification is not found in unirradiated optic nerve gliomas. Following administration of a contrast medium, a moderate to intense enhancement of the tumor is often observed, frequently containing irregular parenchymal lucencies.[21, 24] Bilateral optic nerve gliomas are thought to be characteristic of neurofibromatosis type 1 (Figs. 11-10 and 11-11).[24] Extension of the tumor through the optic foramen commonly results in enlargement of the optic canal. When the epicenter of the tumor involves the optic chiasm, both anterior and posterior components of the glioma may be seen. Such involvement is helpful in differentiating among lesions of the chiasm. Whatever imaging study is done, it must adequately evaluate the entire visual pathway, because frequently not only the optic nerve and chiasm but also the retrochiasmatic visual pathways are involved.[6]

MR Imaging Appearance

When evaluating the visual pathways (specifically the optic nerves) for optic nerve glioma, thin sections (3 mm or less) should be obtained, because excessive slice thickness may make lesions inapparent as a result of volume averaging.[23, 25] Precise anatomic definition of optic nerve gliomas is generally superior on MR imaging compared with CT, especially where the lesion passes through the optic canal (Figs. 11-10 and 11-12).[22] Sagittal MR imaging may give information not available with standard axial or coronal CT scanning techniques. In addition, the sensitivity of MR imaging to extensive visual pathway gliomas with involvement of the chiasm, optic tracts, lateral geniculate bodies, and optic radiations is much greater than that of CT (Fig. 11-12).[26] On MR imaging, a lesion involving the optic nerve is generally well defined, showing enlargement of the nerve (Fig. 11-10). On short TR/TE images, optic nerve gliomas are usually isointense to cortex and hypointense to white matter. Invariably they are hypointense to orbital fat. On long TR/TE images, the lesions demonstrate a mixed to homogeneous appearance that is hyperintense to white matter, cortex, and orbital fat.[27] Following administration of gadolinium contrast material, increased signal intensity on short TR/TE images is often seen (Figs. 11-10 and 11-12). The MR appearance of optic glioma is somewhat variable, depending on whether the tumor grows within the optic nerve (Fig. 11-12) or grows around the optic nerve into the perineural space. In the latter case, when the perineural portion enhances, it may mimic the perioptic meningioma and may be misdiagnosed, especially in the adolescent or adult patient. Intrinsic masses within the optic nerve, such as occult vascular malformations (Fig. 11-13), can be differentiated from intrinsic optic glioma by the presence of blood products on long TR images.

Perioptic Meningioma

Perioptic meningiomas are benign tumors arising from the meningoendothelial cells of the arachnoid. The rests from which these cells arise occur in a variety of locations within both the orbit and the cranial vault. Intraorbital meningiomas occur at the orbital apex, along the course of the optic nerve sheath, or unrelated to the optic nerve, usually in the extraconal space from the periosteum of the orbital wall.[21] Meningiomas make up approximately 5% to 7% of all primary orbital tumors, are more common in females than in males (4 to 1), and appear most frequently in the fourth and fifth decades of life (median age, 38 years).[28] They may occur in children (25% in the first decade), and they are much more frequent in patients with neurofibromatosis type 2 than in the general population.

Clinical Findings

The symptoms the patient displays depend on the size of the tumor and its location within the orbit. Small intracanalicular perioptic meningiomas may be difficult to detect and yet may cause significant visual symptomatology. Proptosis and visual loss are the usual symptoms in patients with perioptic meningiomas.[29] Disk elevation, optic atrophy with central or peripheral scotomata, or both are commonly seen because of the tumor's proximity to the optic nerve. Tumors that occur within the optic canal frequently appear with central scotomata, often without other symptoms.[29]

Pathologic Findings

Of the various histologic types of meningioma, the meningothelial variety is the most common within the orbit. Microscopically, the tumor consists of solid sheets of distinctively central vacuolated cells, with rare mitoses. Within the orbit, other histologic types of meningioma such as fibroblastic, transitional, syncytial, psammomatous, and angioblastic varieties are much less common. The rare orbital angioblastic meningioma is difficult to differentiate from hemangioblastoma and hemangiopericytoma.[24] Regardless of the histology, perioptic meningiomas in children tend to be more aggressive than those in adults. These

childhood tumors are often only partially encapsulated and have a propensity to grow by infiltration, breaking through the dura and involving other orbital structures. Orbital meningiomas, when adjacent to the bony wall, may induce a reactive hyperostosis, whereas those at or near the orbital apex may cause demineralization with enlargement of the optic canal.[28] Optic atrophy with a decrease in the number of axons within the nerve results from compression of the nerve by the tumor. The tumor grows either as an eccentric mass along one side of the optic nerve or as a circumferential lesion. Intratumoral psammomatous calcifications may be present, particularly within highly cellular areas of the tumor.

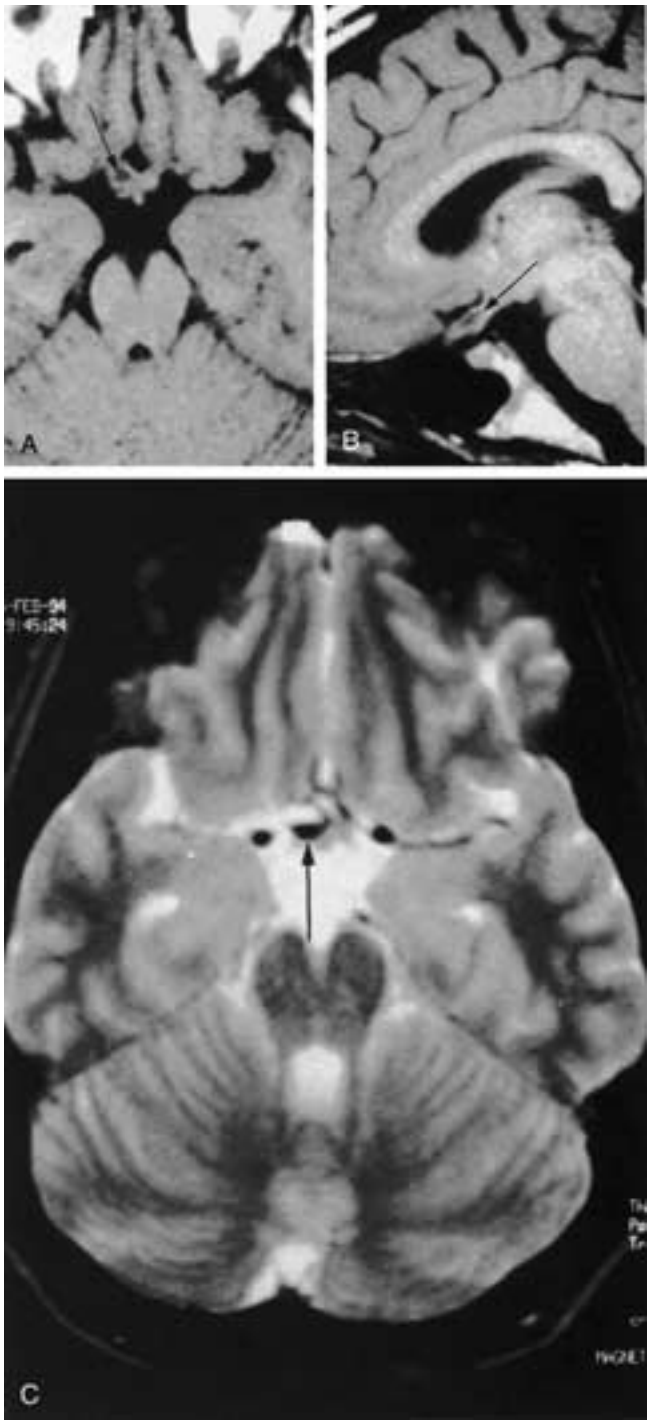

FIGURE 11-13 Occult vascular malformation of the right optic nerve in an 18-year-old female with monocular visual loss in the right eye for more than 1 year. The patient was referred with the diagnosis of right optic glioma. **A** and **B**, Axial and sagittal T1-weighted images without gadolinium enhancement show a hypointense, cystic expansion (*arrow*) of the intracranial portion of the optic nerve. **C**, Axial T2-weighted image shows hypointense blood (*arrow*), dependent within the cyst, the supernatant within the cyst being hyperintense. The findings are consistent with an occult vascular malformation. The same findings were present 1 year before this examination.

VIEW IMAGE

CT Appearance

On CT, perioptic meningiomas (Fig. 11-2) appear either as a localized eccentric mass at the orbital apex[14] or as a well-defined tubular thickening (64%) or fusiform enlargement (23%) of the optic nerve sheath complex.[21, 30–32] Stippled calcification within the tumor is common (Fig. 11-2), helping to differentiate it from the optic nerve glioma. Secondary enlargement of the optic canal, with bony hyperostosis, may be seen if the tumor is located in the appropriate position.[21, 24] Because the detection of calcification and bony change is helpful in making the diagnosis of perioptic meningioma, a noncontrast-enhanced CT scan with very thin sections (1 mm) may be considered superior to nonenhanced MR imaging in evaluating small perioptic lesions.[26] After administration of a contrast medium with CT, moderate to marked enhancement of the tumor is seen. The so-called tram-track sign of perioptic meningioma is caused by uniform enhancement of a circumferential meningioma (Fig. 11-3). This may simulate dural inflammation, a finding that may be present in cases of optic neuritis and idiopathic inflammatory pseudotumor.

MR Imaging Appearance

MR imaging displays the tumor as an abnormally enlarged optic nerve silhouette. Signal characteristics depend on the pulse sequence. On short as well as long TR/TE scans, perioptic meningiomas show diminished signal intensity relative to normal brain tissue.[21] Relative to orbital fat, on short TR/TE images the lesions are hypointense, whereas on long TR/TE images they are isointense. The calcifications within the tumor may be visualized as regions of signal void on MR imaging; however, most frequently intratumoral calcification is not seen. MR imaging may show meningiomatous bone involvement as a region of absence of the expected signal void within an area of cortical bone.[33] Chemical shift artifact, resulting in a dark line on one side of the optic nerve, may mimic calcification. Similarly, the subarachnoid space within the optic nerve sheath may appear dark on appropriate pulse sequences, mimicking circumferential calcification. This may be ruled out by using an appropriate pulse sequence designed to increase the signal intensity of CSF.[6] Gadolinium has become critical (Fig. 11-14B)[33] in the diagnosis of small perioptic tumors. Fat suppression is necessary with thin (2- to 3-mm) T1-weighted images in order to separate the enhancing tumor from the intraconal fat (Fig. 11-15).

Sarcoidosis

Sarcoidosis is a granulomatous disease of unknown cause that involves several organ systems, most commonly

FIGURE 11-14 Perioptic meningioma. **A**, Axial T1-weighted image before administration of gadolinium shows no specific abnormality. **B**, Axial T1-weighted image after intravenous administration of gadolinium shows enhancement of tumor (*arrow*) that extends from the region of the anterior clinoid process on the right, through the optic canal, and along the optic nerve. Surgery revealed a perioptic meningioma.

mediastinal and peripheral lymph nodes, lungs, liver, spleen, skin, eyes, and lacrimal glands.[28, 34, 35] Pathologically, it is characterized by noncaseating granulomas, which may occur in any tissue or organ of the body. Ophthalmic changes caused by sarcoidosis occur in up to 60% of cases.[34] The most frequently involved area within the orbit is the lacrimal gland; however, infiltration may be seen in any orbital structure.[33, 36]

Clinical Findings

Two clinical presentations of sarcoidosis are noted. The subacute form generally occurs in patients under 30 years of age, particularly in women of Swedish, Puerto Rican, and Irish descent, and is characterized by rapid appearance of erythema nodosum, possibly with accompanying polyarthritis in association with bilateral hilar adenopathy. The second form is a chronic disease that affects patients over 30 years of age; the pulmonary parenchyma is involved, and the disease spreads beyond the thorax.[28] In general, the disease is seen predominantly in African Americans 20 to 40 years of age.[34] Patients with subacute sarcoidosis tend to exhibit peripheral and cranial nerve involvement, with the seventh cranial nerve most commonly involved and the optic nerve next most commonly affected. Involvement of the third, fourth, or sixth cranial nerves may produce extraocular muscle palsies. In the chronic form of sarcoidosis, CNS involvement is more common than peripheral nerve involvement, and the optic nerve is much more frequently affected than in the subacute form (recall that the optic nerve is an extension of a central brain tract and not a peripheral nerve). Optic nerve sarcoidosis may occur intracranially, with chiasmal involvement, or in the intracanalicular or intraorbital portions, and optic nerve involvement in this form of the disease may lead to optic atrophy.

Anterior uveitis, the most frequent sign of sarcoidosis, is characteristic of the subacute form of sarcoidosis, whereas a nonspecific granulomatous uveitis occasionally accompanied by cataract or secondary glaucoma is more indicative of the chronic form. Intracranial sarcoidosis is clinically evident in 5% of the cases, whereas 15% of autopsy cases demonstrate CNS involvement.[2] These patients may exhibit papilledema, disk edema secondary to increased intracranial pressure. Optic atrophy may be present as a result of inflammation of the optic nerve, compression by sarcoid granuloma, infarction due to sarcoid vasculitis, or glaucoma caused by intraocular inflammation.

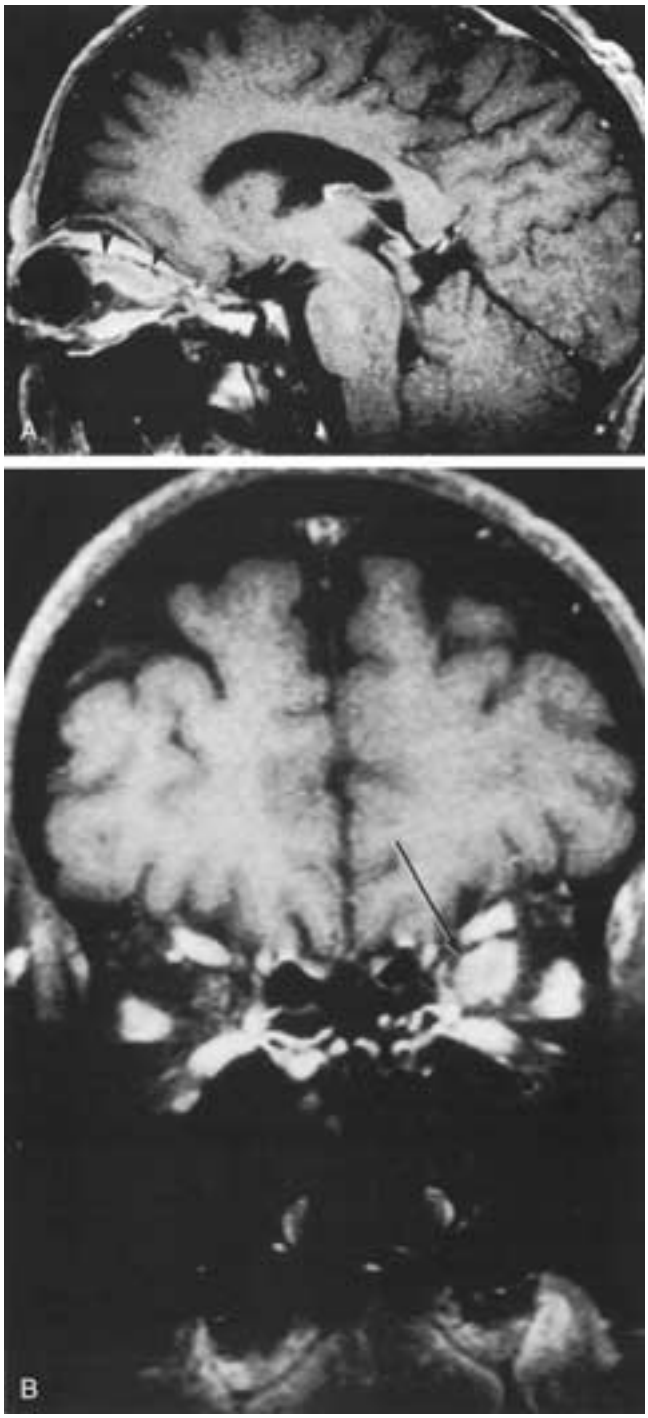
Pathologic Findings

The basic lesion of sarcoidosis is a noncaseating epithelioid cell tubercle. Langerhans' giant cells are seen interspersed within the epithelioid cells centrally, and a thin rim of lymphocytes rings the individual tubercles. Inclusion bodies are characteristically seen within the giant cells in the tubercle. Although, as part of their natural course, the sarcoid granulomas may disappear without any evidence of scarring, they usually heal with sclerosis at the margins of

Copyright © 2003, Mosby, Inc. All rights reserved.

the tubercles, and calcification does not occur during the healing process.[28]

Intracranial involvement by sarcoidosis generally occurs in one of two patterns. The most common one is granulomatous leptomeningitis with involvement of the leptomeninges, including those investing the optic nerves. The second pattern is that of coalescence of sarcoid nodules into distinct parenchymal brain masses.[37] In the leptomeninges, the cranial nerves, pituitary gland, third ventricle, hypothalamus, and (in rare cases) pineal gland are involved.[33, 38] Hydrocephalus may result from sarcoid lesions of the aqueduct, fourth ventricular outlet foramina, or basal meninges, occasionally resulting in vessel obstruction with subsequent infarction.[39]



VIEW IMAGE

FIGURE 11-15 Perioptic meningioma in a 53-year-old male with left monocular visual loss and evidence of optic atrophy on fundoscopic examination. Symptoms had been progressive over a number of years. **A**, Oblique sagittal, fat-suppressed, gadolinium-enhanced T1-weighted MR image shows a mass (*arrowheads*) surrounding the optic nerve, extending from the globe back to the optic canal. **B**, Coronal fat-suppressed, T1-weighted, gadolinium-enhanced MR image shows that the left optic nerve (complex) is enlarged and enhancing (*arrow*).

CT Appearance

Diffuse infiltration of the leptomeninges is the most common CT finding. On the unenhanced study, areas of diffuse, irregularly increased attenuation along the leptomeninges may be seen. However, a normal study is the most frequent finding.[34, 40, 41] With orbital involvement the lacrimal gland may be enlarged, and irregular thickening of the meninges of the optic nerve may be present. Brain parenchymal involvement produces discrete nodules that, on an unenhanced CT scan, may be isodense or slightly hyperdense to the surrounding normal parenchyma. The nodules may be multiple or singular or may even form large, discrete masses upon coalescence. Surrounding edema is usually not present. Following administration of a contrast medium, diffuse, irregular enhancement along the basal cisterns can be seen. The borders of the cortical sulci may enhance similarly as a result of leptomeningeal spread within the perivascular spaces of Virchow-Robin.[34] Homogeneous enhancement of parenchymal nodules also occurs after administration of the contrast medium.[34, 39, 42] Obstructive hydrocephalus may be seen when structures adjacent to the third ventricle or the aqueduct or the outlet foramina of the fourth ventricle are involved. Cranial nerve involvement generally produces fusiform or irregular enlargement of the nerve with homogeneous enhancement after administration of contrast medium.[34] Compression or direct invasion of the cranial nerves may occur as a consequence of infiltration of the basal meninges. Calcification is not a feature of sarcoidosis.[38]

MR Imaging Appearance

Orbital sarcoidosis is evaluated well with MR imaging, which demonstrates a high degree of anatomic detail not seen with CT, particularly in areas where image degradation occurs on CT caused by beam-hardening artifact (i.e., in the intracanalicular and intracranial portions of the optic nerve).[43–47] MR imaging demonstrates sarcoid involvement of the optic nerve as diffuse enlargement of the optic nerve sheath complex of a variable signal intensity that is usually isointense to extraocular muscle on short TR/TE images and minimally hyperintense to orbital fat on long TR/TE images (Fig. 11-16).[33, 36, 48] Lacrimal gland involvement by sarcoid is generally seen as diffuse enlargement of the gland with a signal intensity pattern that may be either low or high on long TR/TE images.[33, 36] The two major pathologic changes of intracranial sarcoid are well demonstrated by MR imaging. They consist of abnormal tissue involving the meninges (Figs. 11-17 and 11-18) and the brain parenchyma (Fig. 11-16) in addition to

hydrocephalus and small areas of infarction.[49] Meningeal involvement by sarcoid tissue is most commonly seen in the region of the basal cisterns as focal areas of high signal intensity tissue on long TR/TE images (Fig. 11-17B). However, the signal intensity characteristics may vary, and the tissue occasionally may be hypointense to normal brain parenchyma on long TR/TE images. Periventricular involvement demonstrates similar signal intensity and is also a common location for visualization of abnormal sarcoid tissue. The parenchymal regions of sarcoidosis also have similar signal characteristics. MR imaging has greater sensitivity than CT for detecting regions of sarcoidosis, [45, 50] and the hydrocephalus associated with sarcoid involvement of the CSF pathway is clearly identified with MR imaging. The site of obstruction responsible for the hydrocephalus may also be determined with MR imaging techniques. Specifically, the absence of a flow void sign within the aqueduct or within the foramina of Magendie or Luschka may indicate these to be the primary sites of obstruction.[51] The use of gadolinium in evaluating sarcoid has proven helpful in demonstrating the extent of meningeal involvement (Figs. 11-17 and 11-18). However, the MR appearance of leptomeningeal sarcoid is not specific; a similar picture may be seen with tuberculosis and other bacterial meningitides such as pneumococcal meningitis (Figs. 11-19 and 11-20). In these circumstances, the clinical picture as well as CSF laboratory studies are important in the differential diagnosis.

Lyme Disease

Lyme disease is a worldwide tick-transmitted spirochetosis with endemic foci in North America and Europe. The spirochete is *Borrelia burgdorferi*, and the ticks that transmit the disease infect both deer and white-footed mice.

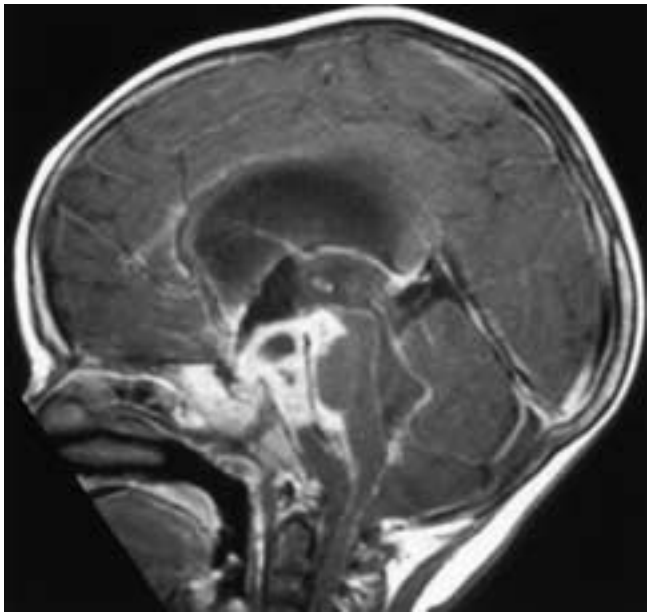

FIGURE 11-19 Tuberculous meningitis. Infant with hydrocephalus and cranial nerve palsies. Sagittal T1-weighted image after gadolinium injection shows a contrast-enhancing suprasellar subarachnoid collection encasing the chiasm and anterior brainstem. Findings are consistent with granulomatous meningitis at the base of the brain.

VIEW IMAGE

FIGURE 11-21 Lyme disease involving the optic chiasm in a 66-year-old female. Coronal (**A**) and axial (**B**) T1-weighted images after contrast injection show enhancement and enlargement of the optic chiasm. **A** is before treatment and **B** is 1 week after the beginning of treatment, showing some response to antibiotic therapy.

Clinical Findings

A bite by an infected tick can result in Lyme disease, causing a variety of manifestations, including arthritis, rash, cardiac manifestations and CNS involvement in 15% to 20% of cases.[52] In the CNS, cranial neuropathies (facial palsy, 80%), meningitis, headache, and cerebral parenchymal involvement resulting in mental changes can occur. [52]

Pathologic Findings

Lymphoplasmacytic perivascular and meningitic infiltration has been recognized in association with a CSF lymphomonocytic pleocytosis. Beyond these manifestations the CNS findings have not been well described pathologically.

CT Appearance

The CT findings that have been recognized are those occurring in the white matter as areas of hypodensity mimicking the lesions of multiple sclerosis. CT is not reliable in recognizing the cranial nerve findings seen on MR imaging as focal enlargement and contrast enhancement.

MR Imaging Appearance

The MR imaging findings most often consist of cranial nerve enhancement after gadolinium injection, with the seventh cranial nerve(s) most frequently involved.[53] However, high signal intensity lesions in the white matter can occur that mimic the lesions of multiple sclerosis.[54] Involvement of the optic nerves and/or chiasm (Fig. 11-21) is seen as swelling with high signal on T2-weighted scans and FLAIR and as contrast enhancement after gadolinium injection.[54] A positive serologic test should be followed by a full course of antibiotics. MR imaging can be used to follow the response to treatment.

Craniopharyngioma

Craniopharyngioma is a benign tumor that arises from remnants of Rathke's pouch. These tumors occur most commonly in a suprasellar location, as well as within the sella turcica. They represent 1% to 3% of intracranial tumors and are found most frequently in children. However, they have two other age peaks, one in young adulthood and one in the fifth decade.[55]

Clinical Findings

Patients with craniopharyngioma most frequently complain of a headache and visual disturbances occur commonly, related to impingement of the tumor on the optic pathway at the level of the chiasm or optic tracts.[56] Hypothalamic and pituitary dysfunction may be seen, and when the tumor occurs in a child, growth failure may result.[57]

Pathologic Findings

Craniopharyngiomas originate from squamous cell epithelial rests arising from Rathke's pouch. They are benign, slow-growing tumors. Grossly, the tumor is well encapsulated and adherent to (and possibly superficially invasive into) the surrounding tissues. As the tumor enlarges, the adjacent structures are compressed, including the optic chiasm anteriorly, the pituitary gland inferiorly, the hypothalamus superiorly, and the elements of the circle of Willis peripherally.[55] The tumor is usually cystic, with interspersed solid areas. The cystic region contains either a liquid or semisolid dark brown, greasy material composed of cholesterol crystals, keratin, and calcified debris. Microscopically, the solid portions of the tumor consist of nests of stratified squamous or columnar epithelium within a fibrous stroma similar to that of the enamel organ of the tooth. For this reason, these tumors are considered to have an adamantinomatous histologic pattern.[57] Approximately 75% of craniopharyngiomas contain significant amounts of calcium.

CT Appearance

On CT, craniopharyngiomas usually appear as rounded, lobulated, or irregularly marginated masses occupying the suprasellar cistern (85% of the time) and occasionally involving the sella turcica (20% of the time).[58] Cystic

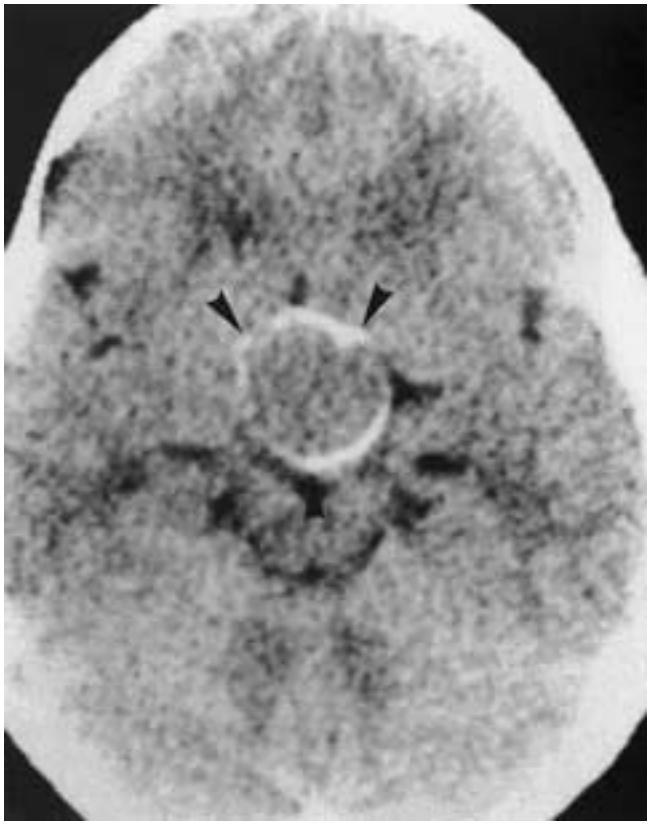
Copyright © 2003, Mosby, Inc. All rights reserved.

components are noted in 85% of the lesions. These cystic regions demonstrate a variable attenuation ranging from markedly hypodense to isodense relative to CSF (Fig. 11-22). The attenuation probably depends on the cholesterol content. Calcification is present in approximately 75% of the cases, varying from 70% to 90% in craniopharyngiomas occurring in children to 35% to 50% in those occurring in adults. The character of the calcification is generally conglomerate, although rim-like calcifications may occur about the cystic portions of the lesion (Fig. 11-22). After administration of a contrast medium, the solid portions of the tumor usually enhance markedly.

MR Imaging Appearance

Because of its multiplanar imaging capabilities, MR imaging displays very well the anatomic configuration of the lesion relative to adjacent brain structures.[57] On short TR/TE images, the tumor generally has increased to intermediate signal intensity as a result of T1 shortening (Fig. 11-23A). This is most likely the result of increased protein concentration (greater than 9000 mg/100 ml), the presence of free methemoglobin, or both.[59] In rare cases the signal intensity is diminished, particularly if the lesion is predominantly cystic (Fig. 11-23C), with a low protein concentration within the cyst fluid. Focal areas of diminished signal intensity on short TR/TE and long TR/TE images may be secondary either to elevated keratin content within the cystic portions of the tumor or to calcification within the solid portions. As a rule, hyperintense signal is seen on long TR/TE images as a result of T2 prolongation.[57, 60] Comparison of CT and MR imaging shows CT's greater sensitivity in displaying calcification; this makes it a more specific radiologic procedure for craniopharyngioma identification, particularly when used in conjunction with the clinical history. MR imaging, on the other hand, is more sensitive to the presence of a tumor and gives a more accurate preoperative demonstration of the extent and location of the tumor, which is important in planning the surgical approach.[57, 60, 61] It has been shown that the craniopharyngioma's wall and solid portions enhance after administration of gadolinium (Fig. 11-24B). Thus, gadolinium increases the sensitivity of MR imaging in the evaluation of craniopharyngiomas, particularly in regard to tumor residual and recurrence after surgical excision.

MR proton spectroscopy has proven useful in differentiating craniopharyngiomas from hypothalamic astrocytomas and pituitary adenomas in children and adolescents.[62] Craniopharyngiomas show a peak in the lipid, lactate part of the scale (1 to 2 ppm), while hypothalamic astrocytomas show elevated choline to Naa ratios (e.g., 2.6 vs. a normal ratio of 0.75) and pituitary adenomas show no metabolites.[62]



VIEW IMAGE

FIGURE 11-22 Craniopharyngioma. Axial nonenhanced CT image shows a suprasellar tumor with a peripheral rim of calcification (*arrowheads*) and a central region that is isodense to brain.

Rathke's Cleft Cyst

Rathke's cleft cyst is a benign lesion consisting of a cystic remnant of Rathke's pouch that occurs within the anterior portion of the sella turcica or the anterior aspect of the suprasellar cistern.

Clinical Findings

Rathke's cleft cysts usually are small and without discernible clinical symptoms. If they are symptomatic, patients may have hypopituitarism, diabetes insipidus, headache, or visual disturbances related to impingement on the visual pathway at the level of the optic chiasm or the optic tracts; however, only 60 symptomatic cases have been reported in the world literature.[63]

Pathologic Findings

The anterior lobe of the pituitary, the pars tuberalis and the pars intermedia, are derived from Rathke's pouch, which is also the origin of the Rathke's cleft cyst. The cyst is generally a simple structure lying primarily within the anterior portion of the sella turcica, occasionally with protrusions into the suprasellar cistern region, forming a dumbbell-shaped lesion. Microscopically, the wall of the cyst in the intrasellar portion is lined by a simple cuboidal epithelium, which may be ciliated, whereas the suprasellar portion may be lined by stratified squamous epithelium.[55] The single-cell layer forming the wall of the cyst often contains goblet cells, and the cystic contents usually have a serous or mucoid consistency, with varying amounts of cellular debris. This variable protein content probably accounts for the variable appearance of the cystic portion of the lesion on CT and MR imaging.

CT Appearance

Rathke's cleft cyst usually appears as a well-circumscribed cystic structure that has a mass effect, lies

within the sella turcica, and occasionally has suprasellar extension.[64] The wall of the cyst is generally thin, and the cyst contents usually are similar to CSF, although they may appear hypodense. The rim of tissue may enhance after administration of a contrast medium, and it occasionally contains small amounts of calcium. More complex cysts display a slightly increased density, with septa partitioning the cystic portion.[63] Differential considerations for the simple form of Rathke's cleft cyst include arachnoid cyst and cystic pituitary adenoma, whereas the more complex cysts may be impossible to differentiate from craniopharyngioma.

MR Imaging Appearance

Simple cysts generally have signal intensity characteristics similar to those of CSF; that is, they usually appear hypointense to brain parenchyma on short TR/TE images and hyperintense to brain parenchyma on long TR/TE pulsing sequences. If the cyst fluid contains significant amounts of cholesterol, increased signal intensity is noted on short TR/TE images, with diminishing intensity on progressively longer TR/TE images. Complex cysts, which represent a transitional form between a simple Rathke's cleft cyst and a craniopharyngioma, demonstrate signal heterogeneity on long TR/TE images, with an isointense to hyperintense signal on short TR/TE images (Fig. 11-25). MR imaging better displays the relationship of the Rathke's cleft cyst to adjacent structures, particularly the optic chiasm and hypothalamus (Fig. 11-26).

Pituitary Adenoma

Pituitary adenomas are benign neoplasms arising within the substance of the pituitary gland. They occur with equivalent frequency in males and females between 20 and 50 years of age. MR imaging has become the procedure of choice for evaluating tumors of the pituitary gland.

Clinical Findings

Adenomas of the pituitary gland can be separated into microadenomas (less than 1 cm in diameter) and macroadenomas (greater than 1 cm in diameter). The microadenomas typically appear with endocrine abnormalities, the specific findings depending on which hormone is being elaborated by the adenoma. Macroadenomas, on the other hand, appear more often with symptoms caused by mass effect, such as those resulting from chiasmatic compression or pituitary insufficiency.

Lateral extension of the pituitary adenoma into the cavernous sinus can involve cranial nerves III, IV, and VI. This can produce motility disturbances on the basis of isolated or combined cranial neuropathies. If there is an acute increase in the size of the adenoma, such as can occur with pituitary apoplexy, there can be rapid lateral expansion and the patient can suffer rapid onset of an ocular motility disturbance, with or without a sudden decrease in vision.

Pathologic Findings

Pituitary adenomas are usually unencapsulated solid tumors that may penetrate adjacent structures.[65] The tumors

FIGURE 11-26 Cyst of Rathke's pouch. Contrast-enhanced coronal T1-weighted image shows a multilobulated intra- and suprasellar cystic mass (*arrowheads*) with one component (*arrow*) isointense to brain. There is no enhancement of the mass. The chiasm was compressed. Hydrocephalus is present.

can contain necrotic, cystic, or hemorrhagic regions and rarely contain calcification.[66] Of these adenomas, 25% to 30% are nonfunctional, 25% are prolactin-secreting tumors, 20% elaborate growth hormone, and 10% secrete adrenocorticotropic hormone (ACTH).[66] Microscopically, the adenomas are composed of sheets and cords of cells with a delicate stroma, and the functional adenomas usually contain highly granulated cells indicative of their cytochemical activity. Ischemia with consequent necrosis and hemorrhage may occur secondary to compromise of the blood supply, which results from compression at the diaphragma sellae. This eventually may cause a rapidly expanding sellar mass, with consequent optic nerve compression, headache, and occasional meningeal irritation. The incidence of malignant degeneration among pituitary adenomas is exceedingly small.

CT Appearance

The specific findings associated with pituitary adenoma vary, depending on the size of the lesion.[67, 68, 69] Microadenomas typically are seen as focal hypodense areas within the surrounding pituitary gland, causing convexity of the upper surface of the gland and an increase in the height of the gland greater than 9 mm. Associated displacement of the infundibulum away from the side of the lesion may be seen, and thinning of the ipsilateral sellar floor may be present. These findings are more often found in lesions elaborating prolactin. Lesions elaborating growth hormone or ACTH may be more difficult to visualize because they tend to be less well defined. Also, the ACTH-producing adenomas may be very small. After administration of a contrast medium, microadenomas tend to be hypodense relative to the surrounding normally enhancing pituitary gland.

Macroadenomas display findings that depend on the size of the lesion (Fig. 11-27). They tend to enlarge the sella, causing sloping of the sellar floor, with possible extension into the sphenoid sinus. Depending on the degree of suprasellar extension, macroadenomas may displace the chiasm, the temporal lobes, and even the third ventricle.[68] After administration of a contrast medium, the macroadenomas generally appear isodense to slightly hypodense compared with the cavernous sinuses. If the lesion is solid, homogeneous enhancement occurs (Fig. 11-28A), whereas cystic or necrotic areas within a lesion tend to remain less dense relative to the remainder of the lesion. Macroadenomas may contain calcification, either homogeneously distributed throughout the tumor or deposited in a rim. If infarction of the tumor occurs, a hypodense area secondary to edema may be seen; alternatively, a hyperdense area secondary to hemorrhage may be seen (Fig. 11-29A). However, these findings are often difficult to delineate on CT.[62]

MR Imaging Appearance

MR imaging usually allows accurate delineation of pituitary adenomas greater than 3 mm.[63] Smaller adenomas may also be diagnosed, but with less reliability.[70] A more specific diagnosis of a sellar mass may be achieved with MR imaging than with CT, and MR imaging is clearly better able to characterize subacute hemorrhage within the tumor.[61, 63, 71] Overall anatomic definition is more accurate with MR imaging than with CT (Figs. 11-29B, 11-30 and 11-31). Equivalent demonstration of sellar or dorsum sellae erosion is noted with the two imaging modalities,[72] but CT is better able than MR imaging to demonstrate intratumoral calcification.

Findings of a pituitary adenoma on MR imaging are similar to those noted on CT. Specifically, the primary findings are an upward bulge on the superior surface of the pituitary gland, with contralateral deviation of the infundibulum and sloping of the ipsilateral sellar floor (Fig. 11-31).[63] On short TR/TE images the adenomas tend to be slightly hypointense to the surrounding normal pituitary gland and may or may not be associated with a mass effect.[63] Occasionally pituitary adenomas may be isointense to the

FIGURE 11-28 Pituitary adenoma in a 40-year-old male, bitemporal visual field defect, and clinical evidence of pituitary insufficiency. **A**, Contrast-enhanced CT image shows a large ovoid, homogeneously enhancing suprasellar mass. The temporal horns are dilated, consistent with early hydrocephalus. **B**, Sagittal T1-weighted MR image without gadolinium enhancement shows the sella turcica to be markedly expanded by a soft-tissue mass that projects into the suprasellar region, obliterating the anterior third ventricle and producing early hydrocephalus by obstructing the foramen of Monro. **C**, Coronal postcontrast-enhanced, T1-weighted MR image shows enhancement throughout the solid tumor.

surrounding normal pituitary tissue.[72] On long TR/TE images the appearance of the adenomas varies,[63] but they may be moderately hyperintense relative to surrounding pituitary tissue.[72] Pituitary adenomas usually demonstrate homogeneous signal intensity; however, occasionally they are of mixed intensity due to necrosis, hemorrhage, or cyst formations.[72]

Suprasellar extension with impingement on and displacement of the optic chiasm is best demonstrated on coronal and sagittal sections (Fig. 11-30).[61, 68] Coronal sections are also better for demonstrating tumor extension into the cavernous sinuses (Fig. 11-32).[73] Demonstration of extension into the cavernous sinuses is often difficult with MR imaging because the medial wall of the cavernous sinus is very thin, and violation of this tissue plane may be difficult to see. However, when the tumor extends around the intracavernous carotid artery, displacing it medially, or is found above it, displacing it downward, invasion of the cavernous sinus can be diagnosed.

There is no evidence of a difference in signal intensity between secretory and nonsecretory pituitary adenomas.[63] Cystic pituitary adenomas characteristically display high signal intensity on long TR/TE images and low signal intensity on short TR/TE images at the site of the cyst (Fig. 11-31). Subacutely hemorrhagic pituitary adenomas display high signal intensity on short TR/TE images because of the paramagnetic effect of methemoglobin (Fig. 11-33).[74] On short TR/TE images, after administration of a paramagnetic contrast agent such as gadolinium, a pituitary microadenoma is shown as a focal area of hypointensity relative to the surrounding enhancing normal pituitary tissue.[75, 76] This is true only if the images are acquired very early after administration of the contrast medium.[53] Dynamic scanning during contrast injection in the coronal plane through one thin section aids in diagnosis. On images obtained late after administration of the contrast medium, the microadenoma enhances and may not be distinguished from the normal pituitary gland. Macroadenomas show contrast enhancement.

Following performance of a transsphenoidal hypophysectomy, one possible complication is herniation of the optic chiasm, of the intracranial portion of the optic nerve, and/or

High signal intensity more to the left of the midline represents an area of cystic necrosis, whereas low signal intensity represents deoxyhemoglobin.

of the proximal aspect of the optic tracts into the surgically created empty sella. The herniation of the suprasellar visual system is well delineated with MR imaging. A visual deficit may or may not be present. The degree of deficit bears no relationship to the severity of herniation as seen on MR imaging.[77]

Aneurysms

Aneurysms may be responsible for visual symptoms if they impinge directly on the visual pathway.[78, 79] The most common aneurysms to do this arise from the internal carotid artery at the origin of the ophthalmic artery. Aneurysms

occurring in this location compress either the optic chiasm, the intracranial portion of the optic nerve, or the proximal portion of the optic tract.

Clinical Findings

Aneurysms arising from the internal carotid artery at the origin of the ophthalmic artery most often appear in patients between 50 and 70 years of age, and most patients are female. Of the aneurysms in this location, 75% are discovered at the time of angiographic evaluation for subarachnoid hemorrhage that has originated from another

aneurysm. However, in approximately 25% of patients with these aneurysms, the presentation is solely because of visual symptoms. The aneurysms associated with visual symptoms are often found to be large (greater than 2.5 cm in diameter).[80, 81] Also, more than half of the patients with these aneurysms have at least one other intracranial aneurysm, and the most common site of the additional aneurysm is the same site on the contralateral side.[82]

A diverse range of visual abnormalities is encountered, but visual acuity is nearly always impaired. This usually begins on the side of the aneurysm and may progress over months or years, leading eventually to blindness. Visual field abnormalities are also diverse because of the variety of ways in which the optic nerves and chiasm can be displaced by the aneurysm. Most commonly, unilateral or bilateral temporal field defects are seen, and the clinical presentation of aneurysms in this location can mimic that of pituitary tumors.

Pathologic Findings

Grossly, these aneurysms tend to be saccular ones arising from the upper surface of the internal carotid artery at the origin of the ophthalmic artery.[83] Microscopically, within the aneurysm dome, there is fragmentation of the interna of the vessel with degeneration of the smooth muscle wall. Frequently the dome of the aneurysm contains layers of adherent thrombus of varying ages.

CT Appearance

Although aneurysms at the internal carotid-ophthalmic artery junction that cause visual pathway symptoms are usually intact, they are most frequently discovered when the patient seeks help for symptoms of a subarachnoid hemorrhage. Therefore, the CT findings of an aneurysm in this location often coincide with the findings of subarachnoid hemorrhage, which most commonly consist of high-density material lying within the sulci and cisternal spaces. Depending on the location of the ruptured aneurysm, high-density material reflecting hemorrhage may be seen within the ventricular system or within the brain parenchyma itself.

The appearance of the aneurysm causing visual pathway symptoms depends on whether there is partial thrombosis within the aneurysmal dome. If no thrombus is present, the aneurysm usually appears as a rounded area of slightly increased density lying cephalad to the cavernous sinus adjacent to the optic chiasm. The structures in the region may be displaced. After injection of a contrast medium, there is homogeneous enhancement of the aneurysm (Fig. 11-34), and rim calcification may or may not be present (Fig. 11-35). A partially thrombosed aneurysm appears on an unenhanced CT scan as a well-circumscribed mass with an isodense periphery and central hyperdensity. The hyperdense central patent lumen enhances upon administration of contrast medium, and a peripheral rim of enhancement may occur because of increased vascularity within the aneurysm wall. If the aneurysm is completely thrombosed, only isodense thrombotic material may be seen within its central portion.[84] Three-dimensional (3D) CT angiography is emerging as a useful technique for evaluation of intracranial aneurysms. Utilizing a continuous peripheral intravenous infusion of contrast material (1 ml/sec for a total dose of 2 ml/kg), rapid dynamic thin-section CT images are obtained through the circle of Willis. Surface-rendering 3D reconstruction algorithm software is then used to produce images of the circle of Willis, the cavernous and supraclinoid internal carotid arteries, and any associated aneurysms. Rotational evaluation of the produced images is then performed. This technique provides additional information regarding the position of an aneurysm relative to adjacent vascular and bony structures and, by inference, to adjacent neural structures, without the use of more contrast or imaging time than is required for a routine contrast-enhanced head CT scan.[85]

MR Imaging Appearance

Compared with CT, MR imaging more precisely characterizes giant aneurysms and defines their location relative to that of adjacent anatomic structures. However, MR imaging is much less sensitive than CT for detecting acute subarachnoid hemorrhage. Fluid-attenuated inversion recovery imaging is useful in showing subarachnoid hemorrhage on MR imaging as high signal intensity within cisterns and sulci between 3 to 45 days after the bleed.[86] Therefore, in the setting of symptoms suggesting acute subarachnoid hemorrhage, CT is the imaging modality of choice. However, MR angiography (MRA) is being used as a screening technique for detection and delineation of intracranial aneurysms in asymptomatic high-risk patient groups, and aneurysms as

Copyright © 2003, Mosby, Inc. All rights reserved.

small as 3 to 4 mm in diameter can be visualized. The sensitivity of MRA for detection of intracranial aneurysms varies between 70% and 95% (Fig. 11-36). Conventional contrast angiography remains the most sensitive modality for detecting intracranial aneurysms.[87, 88, 89] Nevertheless, this modality is limited by its ability to demonstrate only the patent portions of the lumen of the aneurysm, and because many aneurysms contain thrombus, which partially or completely obliterates the lumen, the full extent of the lesion often cannot be defined by conventional angiography.

The characteristic appearance of a partially thrombosed aneurysm on MR imaging has been well described.[84, 88, 90, 91] On spin-echo imaging, partially thrombosed aneurysms demonstrate a flow phenomenon, usually a flow void, within the patent portion of the lumen. The laminated thrombus along the margins of the aneurysm dome exhibits mixed signal intensities, reflecting the various stages of clot formation. A periluminal rim of hyperintensity is usually seen, reflecting methemoglobin surrounding the patent portion of the lumen (Fig. 11-34B). The parent vessel (i.e., the internal carotid artery) shows a signal void because of high-velocity flow. Gradient echo acquisition images, which display high-velocity flow as regions of high signal intensity, demonstrate blood flow within the lumen of the parent vessel and within the patent portion of the lumen of the aneurysm. On spin-echo images, aneurysms with no thrombus formation appear as areas of signal void (Figs. 11-37 and 11-38) and on gradient echo acquisition images as areas of high signal intensity. If the aneurysm is completely thrombosed, mixed signal intensity caused by various stages of clot formation is seen within the aneurysmal mass on spin-echo images (Fig. 11-38).

The relationship of the aneurysm to the elements of the visual pathway is delineated with MR imaging. The coronal plane is helpful in showing the relationship of the aneurysm to the optic chiasm, nerve, and tract, as well as the aneurysm's relationship to the structures of the sella turcica and the cavernous sinus. Additionally, mass lesions (other than aneurysms) impinging on the optic chiasm are well delineated with coronal MR imaging.[92, 93]

Infarction

Cerebral infarction, a localized area of tissue necrosis produced by circulatory insufficiency, is the most common

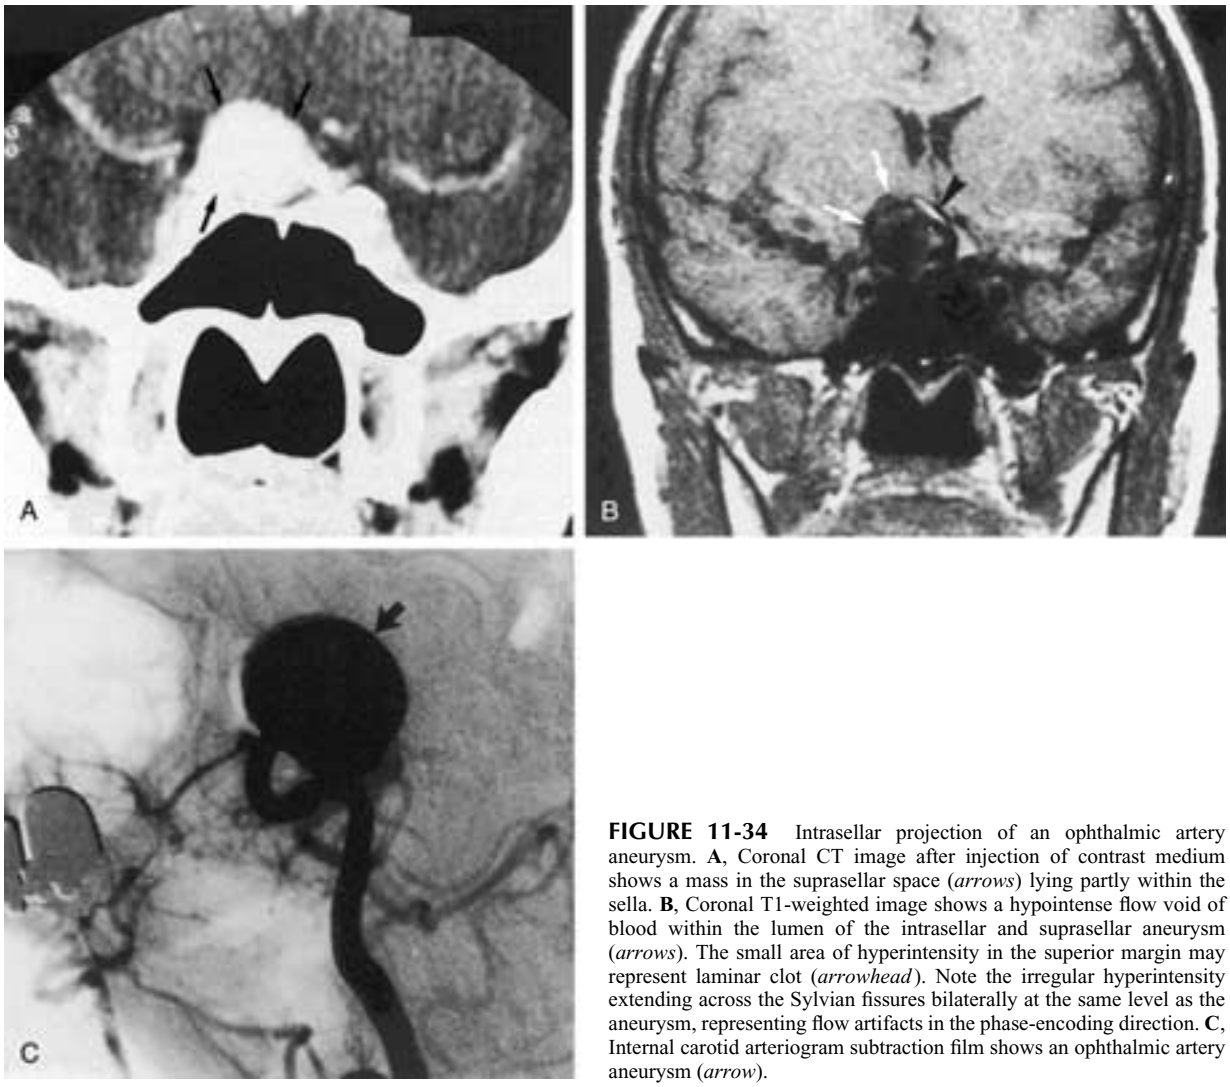

FIGURE 11-34 Intrasellar projection of an ophthalmic artery aneurysm. **A**, Coronal CT image after injection of contrast medium shows a mass in the suprasellar space (*arrows*) lying partly within the sella. **B**, Coronal T1-weighted image shows a hypointense flow void of blood within the lumen of the intrasellar and suprasellar aneurysm (*arrows*). pathologic disorder affecting the CNS. Cerebral infarctions may be further subdivided into ischemic and hemorrhagic forms. They may be due to arteriosclerosis, which may or may not be associated with thrombosis, emboli, or venoocclusive disease.

Clinical Findings

Circulatory insufficiency may be caused by involvement of the anterior cerebral circulation (internal carotid arteries and their branches) or the posterior cerebral circulation (the vertebral basilar system). Amaurosis fugax, or transient loss of vision in one eye, is the most common ocular symptom of internal carotid artery ischemia. Specific findings vary from altitudinal or arcuate visual field defects to complete loss of light perception in the affected eye. Vision may return after a few minutes, but permanent visual loss because of central retinal artery occlusion can and often does occur. Cholesterol emboli may be found in association with amaurosis fugax, and ophthalmoscopic evaluation reveals these emboli within the retinal arterioles as characteristic bright yellowish-orange plaques. Because the internal carotid artery and its branches supply the frontal lobes, parietal lobes, portions of the temporal lobes, the corpus striatum, and the internal capsule, an occlusion may produce a variety of contralateral motor and sensory dysfunctions in addition to the visual findings.

Insufficiency of the circulation of the vertebral basilar system causes transient ischemic attack or infarction with complex and diverse neurologic symptoms. In addition to ocular symptoms, vertigo and nausea may be present if the cochlear vestibular system is involved. Involvement of the auditory system may produce tinnitus or partial deafness. Headache, dysphagia, dysarthria, and hiccuping may also occur. The ocular symptoms include transient or permanent homonymous hemianopsia and possibly blurred vision with diplopia. The homonymous hemianopsia arises as a result of infarction of the occipital lobe's visual cortex, which is fed by branches of the posterior cerebral artery. Diplopia occurs because vascular insufficiency produces infarction in the fasciculi connecting the brainstem nuclei or in the brainstem nuclei of the third, fourth, and sixth cranial nerves. Internuclear ophthalmoplegia may occur as a result of interruption of the vascular supply to the medial longitudinal fasciculus (Figs. 11-39 and 11-40), but this does not usually manifest as diplopia.

Pathologic Findings

Infarcts may be divided into two basic categories, depending on the amount of hemorrhage that occurs in the involved tissue. Infarction caused by thrombotic events generally produces an anemic or nonhemorrhagic infarction, whereas infarctions of embolic cause often are associated with a variable degree of hemorrhage into the interstitial space.[47, 56] Infarctions affecting the elements of the visual pathway are not dissimilar to infarctions in other regions of the brain, showing no discernible histologic differences. Their distinguishing factor is their position relative to the various portions of the visual pathway. The mechanism of infarction, whether hemorrhagic or anemic, is the same: deprivation of blood supply to a given area. In hemorrhagic infarctions, transitory occlusion of a vessel results in ischemic change of the brain tissue and the involved blood vessel's walls. When the blood supply is reestablished, blood elements penetrate the damaged vascular wall into the interstitial space, creating parenchymal hemorrhage.

The earliest grossly visible change in the evolution of an ischemic infarction is a slight discoloration and softening of the affected tissue, which occurs approximately 6 to 8 hours after occlusion of the vessel. Histologically, at this point there is diffuse swelling of the neurons, with resultant

cytotoxic edema.[94] At 48 to 72 hours after occlusion of the vessel, tissue integrity is lost in the affected region and the surrounding tissue displays diffuse vasogenic edema. The combination of cytotoxic and vasogenic edema, with the resultant mass effect, may produce cerebral herniations that, depending on their site of occurrence, may damage neural transmission along the visual pathway (e.g., optic tract with temporal lobe herniation). Eventually, if the area of infarction is large enough, there is liquefaction and cyst formation surrounded by firm glial tissue. Histologically, in the final stages of evolution of an anemic infarction, gliosis both replaces and surrounds the necrotic region. Infarct evolution may take weeks to many months.[56] In addition to being associated with emboli, hemorrhagic

FIGURE 11-38 Thrombosed aneurysm. Coronal T1-weighted image shows a suprasellar mass composed of high signal intensity methemoglobin.

infarction may be seen in association with hypertension and venous occlusion (Fig. 11-40), bleeding dyscrasias, or anticoagulant administration.[95] After extravasation of blood into the interstitial tissue, significant mass effect may occur, resulting in herniation. In fact, hemorrhagic infarction may result from a herniation that caused temporary compression of a trapped blood vessel. With reperfusion of the vessel on reduction of the herniation, blood suffuses through the damaged vascular wall into the infarcted brain.

CT Appearance

The effects of an ischemic infarction may be visible as early as 3 to 6 hours after the ictus (Fig. 11-41A).[96] Occasionally, a thromboembolism within the vessel serving the area of infarction may be visualized on a CT scan as a region of hyperdensity in the vessel lumen before development of subsequent parenchymal changes (Fig. 11-42A).[97, 98] This finding is not, however, a reliable indicator of vessel occlusion or subsequent infarction, as it may be due to increased hematocrit or calcification within the vessel walls, as can occur with diabetes or hypertension.[99] However, changes may be seen more reliably between 8 and 24 hours after the onset of ischemia. These changes are regions of hypodensity in the involved vascular distribution, including both white and gray matter (Fig. 11-40A). The region of hypodensity, which represents intracellular (cytotoxic) edema, becomes more sharply defined over the next several days. Cytotoxic edema and tissue necrosis reach their maximum between the third and fifth days after the ictus, producing variable amounts of mass effect. In occipital lobe infarctions or infarctions involving the optic radiations, this may be perceived as effacement of the adjacent sulci and/or atrium and occipital horn of the lateral ventricle. Larger infarctions may cause marked mass effect and result in descending transtentorial herniation with occlusion of the posterior cerebral artery when it is trapped on the tentorial edge. Occlusion of the posterior cerebral artery results in infarction of the posterior temporal and occipital lobes.

Vasogenic (interstitial) edema is seen more often with embolic infarction. This follows reperfusion of the affected area, usually occurs 2 to 14 days after the acute event, and is responsible for a significant degree of mass effect. Approximately 1 month after the ictus, cystic cavitation in the infarcted region occurs pathologically and is responsible for increasingly sharp definition of the region of the infarct. The infarcted region also becomes smaller because of progression of gliosis, and there is resultant increase in the depth of the adjacent sulci and enlargement of the adjacent ventricle. Hemorrhagic infarctions, which result from embolic phenomena, overall are less frequent, representing only 20% of cases. The hemorrhage, when visible, is seen on an unenhanced CT scan as a region of high density involving the cortex or the deep white matter.

MR Imaging Appearance

MR imaging is the most valuable imaging tool in the evaluation of cerebral infarction because of its high sensitivity to increased tissue water content. The sensitivity of MR imaging in the early detection of infarction is much higher than that of CT.[100–103] Experimentally, infarctions may be detected with MR imaging 1 to 2 hours after the onset of ischemia.[104, 105] The earliest detectable changes are vascular flow-related abnormalities including absence of the flow void normally seen within the cerebral vessels. Also, on administration of gadolinium DTPA, enhancement of the arterial wall may occur, and these findings may be seen within minutes of onset. Early brain swelling can be detected on short TR/short TE images without associated parenchymal signal intensity changes on T2-weighted images.[105, 106] Diffusion weighted MR imaging, which evaluates local water mobility in vivo, can detect alterations in the involved brain parenchyma before the appearance of signal intensity changes on conventional T1-weighted and T2-weighted spin-echo images (Figs. 11-41A and 11-43).[94, 101, 102, 107, 108] The earliest parenchymal signal changes visible are caused by a prolongation of both T1 and T2 relaxation times, with resultant high signal intensity in the region of infarction on long TR/long TE images (Figs. 11-42C and 11-44A) and low signal intensity in the same region on short TR/short TE sequences (Fig. 11-45B).[109] This is frequently visible 6 to 12 hours after the onset of symptoms and is attributable to the development of cytotoxic edema. With further evolution of the infarction, absolute T1 and T2 prolongation becomes somewhat diminished, and only a slight alteration of signal intensity results in the affected area.[110] The mass effect produced by the region of infarction is clearly identified with MR imaging, with greater anatomic delineation of affected structures than is seen on CT. Contrast enhancement of the region may be demonstrated as early as 16 to 18 hours after the ictus and may be exaggerated in character.[105, 106, 111] Again, the region of enhancement correlates with areas of breakdown in the blood-brain barrier.[111, 112] Interestingly, as

edema and mass effect develop, the rapidity with which enhancement occurs declines, presumably as a result of compression of the microvasculature. The regions of enhancement following administration of gadolinium are seen as areas of increased signal intensity on short TR/TE images (Fig. 11-44B). Brain parenchymal change secondary to ischemia caused by vasculitis shows the same basic characteristics with regard to signal intensity as ischemia from either embolic or thrombotic phenomena. However, there is a difference in distribution in that the regions of ischemia are more diffuse throughout the brain, tending to occur in the regions of gray and white matter interface.

Hemorrhagic infarction may be demonstrated as areas of high signal intensity on short TR/TE images (Fig. 11-46B) within the cortex or deep gray matter structures once deoxyhemoglobin within the extravasated blood has been oxidized to methemoglobin.[9] As evolution of the infarction proceeds and cystic encephalomalacia develops, the associated parenchymal volume loss is clearly delineated with MR imaging. Gliosis and demyelination within white matter tracts result in T2 prolongation and, consequently, high signal intensity in the affected areas on long TR/long TE images. Both deoxyhemoglobin and intracellular methemoglobin, as well as hemosiderin, produce loss of signal on T2-weighted images (Figs. 11-40B and 11-47).

Demyelinating Disease

The most common form of demyelinating disease to affect the optic pathway is multiple sclerosis. The characteristic changes seen in demyelination are caused by both plaque formation and gliosis, with resultant alteration in the appearance of the involved parenchyma. The neurophysiologic consequences of the loss of myelin are based on impaired transmission of neural impulses passing through the affected area.

Clinical Findings

Multiple sclerosis has a wide variety of signs and symptoms, which characteristically localize to at least two different anatomic areas within the CNS and occur with a series of relapses and remissions, separated by at least 1

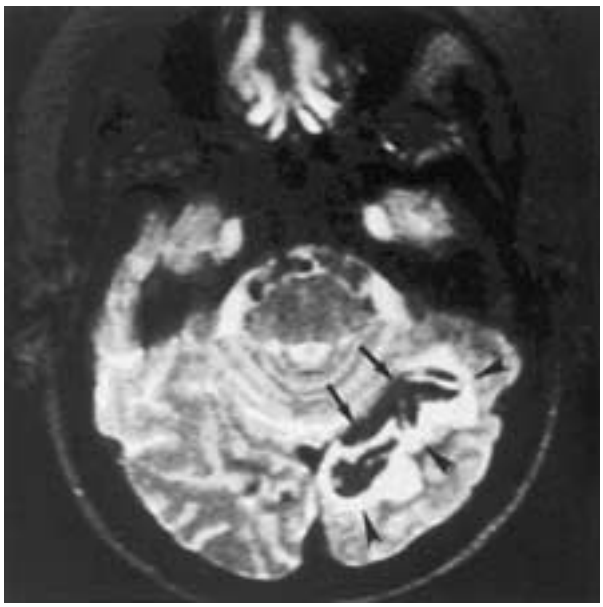

FIGURE 11-47 Hemorrhagic infarct. Axial T2-weighted image shows marked hypointensity of deoxyhemoglobin (*arrows*) in the cortex of portions of a hemorrhagic infarction. Surrounding hyperintensity is present (*arrowheads*).

month.[113] Initially the diagnosis may be difficult to confirm, since the presentation may be caused by a single lesion, or the course may be slowly progressive and not intermittent. Multiple sclerosis most characteristically affects patients between 10 and 50 years of age who reside in northern Europe or the northern United States, and females are affected more frequently than males in a ratio of 1.4 to 1.[114]

Approximately half of patients with multiple sclerosis show clinical signs of optic nerve involvement. Visual evoked responses and electrophysiologic tests of optic nerve and pathway function are positive in approximately 90% of patients with multiple sclerosis. However, only 20% of patients show isolated optic neuritis as their initial clinical symptom.[19] Visual involvement, when present, is typically unilateral, with dense regions of visual loss within the visual fields. Impaired color perception, ocular muscle palsies, and nystagmus are common, and internuclear ophthalmoplegia occasionally is present. Adrenal leukodystrophy (ADL) and Krabbe's disease are examples of dysmyelinating diseases that may cause visual symptoms and involve the visual pathway. ADL usually appears during childhood, with progressive ataxia and loss of hearing and sight. Patients with Krabbe's disease may show symptoms of developmental delay, irritability, and spasticity, often beginning at 3 to 6 months of age.

Pathologic Findings

In multiple sclerosis, the areas of demyelination are seen as focal lesions with well-circumscribed margins. Successive histologic changes occur, consisting of demyelination, a microglial reaction, and then astrocytic proliferation.[22] In the initial stages, oligodendrocytes and the myelin sheaths degenerate, without change in the axon. At this time, an associated vascular congestion with perivascular lymphocytic and plasma cell infiltrates is present. As a result, swelling is present in the acute stage of the inflammation. Later, microglia phagocytize the myelin debris, and this debris stimulates an intense gliosis that forms a firm glial scar in the late stage. Schilder's disease is characterized by large, symmetric zones of demyelination, with degeneration of neural fibers and gliosis. These zones occur throughout the CNS, including the optic nerve and optic radiation.[22] Histopathologically, the lesions are identical to those seen in multiple sclerosis.[115] Krabbe's disease, or globoid cell leukodystrophy, is caused by a deficiency of galactocerebroside beta-galactosidase, which leads to abnormal accumulation of galactoside and its derivative psychosine, which is toxic to oligodendroglial cells. As a consequence, multinucleated globoid cells (macrophages) accumulate in the white matter and are associated with extensive demyelination and astrogliosis.[116]

CT Appearance

The plaques of multiple sclerosis are sometimes detectable by nonenhanced CT as hypodense lesions within the periventricular white matter (Fig. 11-48). Occasionally, the plaques are large and demonstrate mass effect. However, they usually are less than 1.5 cm in greatest dimension. In approximately 5% of cases, multiple sclerosis plaques may be seen within the cortical gray matter or deep gray matter of the cerebral hemispheres.[117] After administration of a contrast medium, plaques in the acute phase may demonstrate enhancement. However, enhancement patterns vary, with none being characteristic of multiple sclerosis. High doses of contrast media have been used to increase the sensitivity of CT in the detection of multiple sclerosis plaques.[118] Steroid administration, however, suppresses the enhancement of acute multiple sclerosis plaques because of stabilization of the blood-brain barrier. With chronic multiple sclerosis, generalized cerebral atrophy may be seen as a result of extensive gliosis.

In adolescents with MS, the lesions observed tend to be more numerous and often confluent with a greater likelihood of infratentorial involvement and a decreased incidence of cortical atrophy.[119] The appearance of Schilder's disease on CT has been described as large, confluent areas of hypodensity within the deep cerebral hemispheric white matter, particularly the centrum semiovale. These areas may show peripheral contrast enhancement. CT scans of patients with Krabbe's disease typically demonstrate areas of low density in the cerebellum deep white matter, medial and lateral to the dentate nuclei. Interestingly, areas of increased density are noted symmetrically involving the thalami and subthalami, with extension to the corona radiata.[116, 120]

MR Imaging Appearance

Because MR imaging is the most sensitive method of evaluation for patients with multiple sclerosis, it has replaced CT in the diagnosis and follow-up of patients with this disease.[113, 114, 121–126]

Multiple sclerosis lesions characteristically demonstrate T2 prolongation, with consequent high signal intensity of the affected areas on long TR/TE scanning sequences (Fig. 11-48).[127] The plaques usually are located within the periventricular white matter (Fig. 11-49). The finger-like extensions radiating away from the lateral angle of the lateral ventricle have been labeled *Dawson's fingers*.[125] These are well seen on FLAIR images.[125] However, because of the sensitivity of MR imaging, increasingly, more plaques have been detected within the white matter of the cerebellum, brainstem, and spinal cord.[128–130] The activity of the plaques is difficult to ascertain. With intravenous administration of gadolinium, enhancement may be seen at the site of acute demyelination, with breakdown of the blood-brain barrier.[131–133] Additionally, enhancement of the leptomeninges may be seen as an inconstant occurrence. The cause and significance of plaque enhancement are in dispute; consequently, they cannot be taken as unequivocal supportive evidence of the presence or absence of MS or as an indicator of the activity of the disease process.[133–135] MR proton spectroscopy is able to differentiate areas of demyelination from regions of disrupted blood-brain barrier and consequent edema, both of which may exhibit enhancement following gadolinium DTPA administration. Proton spectroscopy (MRS) appears to be a more sensitive indicator of the true time course of demyelination in MS.[131] Short inversion time (inversion recovery sequences [STIR]), as well as other fat-suppressed MR techniques, are useful for evaluating the optic nerve in patients with clinically diagnosed optic neuritis[136] by demonstrating the plaque responsible for the observed clinical findings (Fig. 11-50B).[137, 138] However, visual potentials remain more sensitive than MR imaging for detection of optic nerve lesions. The MR imaging findings in Krabbe's disease appear to be

variable but usually consist of high signal intensity within the cerebral deep white matter on long TR/TE images. There does not appear to be a reproducible correlation between the areas of high density in the deep gray matter and deep white matter in the supratentorial brain demonstrated on CT and the alterations in these areas on MRS. Consequently, CT is used to demonstrate the characteristic changes in this disease.[116]

Cerebral Neoplastic Disease

Intracranial tumors affect the visual pathway either by disruption of the neural connections or by exertion of a mass effect, which causes distortion and subsequently impairs the functioning of the visual pathway. An extensive variety of neoplasms may involve the supratentorial brain and consequently the visual pathway.

VIEW IMAGE

FIGURE 11-49 Multiple sclerosis. **A** and **B**, Axial and sagittal FLAIR images show multiple high-intensity multiple sclerosis plaques.

Clinical Findings

The location of a particular neoplasm within the brain often can be determined by clinical signs and symptoms. Large tumors that raise intracranial pressure result in papilledema. Hemiplegia is present if the tumor involves the primary motor cortex. Neoplasms within the parietal lobe often result in visual field defects, particularly those involving the superior parietal optic radiations and thus affecting the inferior quadrant of the contralateral visual field. If the neoplasm involves the angular gyrus of the dominant hemisphere, there may be an inability to recognize printed words (alexia) and an inability to write (agraphia).

FIGURE 11-51 Suprasellar meningioma arising from the planum sphenoidale and diaphragma sellae in a 55-year-old female with bitemporal hemianopsia. **A**, Sagittal T1-weighted MR image following gadolinium injection shows enhancement of a suprasellar mass (*arrows*) that compresses the optic chiasm. **B**, Axial T1-weighted MR image after gadolinium injection shows the anterioposterior and lateral extent of the mass.

Within the temporal lobe, neoplasms can produce superior homonymous quadrantinopsia. If the tumor occurs at the confluence of the dominant frontal, temporal, and parietal lobes, an expressive aphasia frequently is present. Tumors occupying the occipital lobe often cause a congruous contralateral homonymous hemianopsia. If the tumor occupies the association areas of the occipital lobe, the patient may be unable to recognize familiar people (pragmatagnosia). Other clinical findings with intracranial neoplasm include morning headache, nausea, lethargy, and impaired consciousness, depending on the size and location of the tumor. Papilledema may be observed in patients with tumors anywhere in the supratentorial brain.

Pathologic Findings

A wide variety of different tumor types may involve the supratentorial brain and thus the visual pathway.[139] In general terms, the tissue types may be derived from the neural glia, which includes the astrocytes and oligodendrocytes, from the ependyma and its homologues, neurons, primitive undifferentiated cells, and meninges. The tumors may also be metastatic from other regions of the body. Tumors derived from astrocytes include astrocytomas, juvenile pilocytic astrocytomas, and oligodendrogliomas. Astrocytomas range from well-differentiated, histologically benign lesions to highly aggressive anaplastic forms such as glioblastoma multiforme. Intracranial meningiomas arise from the dura, impairing the visual pathway by exertion of a mass effect (Fig. 11-51). Epidermoid tumors arise from cell rests within the suprasellar cistern, enlarging to produce masses that can compress the optic chiasm (Fig. 11-52). FLAIR shows higher signal intensity in the epidermoid tumors than in arachnoid cysts, aiding in their diagnosis (Fig. 11-52).[140–142] Metastatic deposits to the brain from distant primary tumors are responsible for 20% to 25% of all intracranial tumors. The most frequent cell types are bronchogenic and breast carcinomas (Fig. 11-53). Metastatic foci usually are multiple and are found most frequently at the junction of the gray and white matter. The brain tissue surrounding the metastatic focus may show a high degree of vasogenic edema. Microscopically, the metastatic foci are usually identical to the primary neoplasm.

CT Appearance

On CT, intracranial neoplasms are most often identified as mass lesions with or without contrast enhancement and with or without varying degrees of peritumoral edema. Depending on the tumor's location, there may be associated hydrocephalus or other physical distortion of the neuraxis. Astrocytomas are usually isodense to hypodense to normal brain parenchyma on an unenhanced CT scan. The amount of peritumoral edema frequently reflects the grade of the tumor, as does the degree of enhancement after administration of a contrast medium. More aggressive tumor types, in general, demonstrate a greater degree of enhancement and more peritumoral vasogenic edema. Glioblastoma multiforme often demonstrates intense enhancement in a mixed or ring enhancing pattern and may have a markedly irregular margin (Fig. 11-54). Oligodendrogliomas tend to be of high density before administration of a contrast medium and to contain calcification in more than 90% of cases except in the pediatric population, in which calcification is seen in approximately 40% of cases (Fig. 11-55).[143, 144] On plain CT, meningiomas are usually hyperdense relative to normal brain parenchyma. Calcification is found in approximately 20% of cases. Peritumoral edema may be present, and enhancement is usually homogeneous and intense. Metastatic lesions may be either single or multiple and vary in size.[145] From 3% to 14% of metastatic deposits contain intratumoral hemorrhage.[146] The metastatic lesions on an unenhanced scan are hypodense to surrounding brain unless they contain intratumoral hemorrhage, and edema is almost always present to some degree. Enhancement characteristics vary, but enhancement is almost always present (97%).[145]

MR Imaging Appearance

In general, MR imaging demonstrates greater sensitivity in tumor detection than does CT.[147] With the exception of the demonstration of calcification and bone abnormalities associated with intracranial tumors, MR better characterizes a tumor once it is detected. With its lack of beam-hardening artifacts, direct multiplanar imaging, and greater contrast sensitivity, MR imaging better depicts the anatomic extent of a tumor than does CT. Acquisition of gadolinium-DTPA–enhanced images of brain neoplasms helps to define the integrity of the blood-brain barrier within the lesion and thus helps to characterize the tumor more completely and limit the differential diagnosis.[148, 149] The appearance of the various tumor types on MR imaging is a function of many factors, including variations in water content; the presence or absence of hemorrhage, fat, calcification, or paramagnetic material such as melanin; and the degree of vascularity of the tumor.[150]

Astrocytomas appear as mass lesions of high signal intensity on long TR/TE images (Fig. 11-56). Peritumoral edema may be seen on long TR/TE images as an area of high signal intensity spreading through the adjacent white matter. It is difficult to differentiate edema from tumor extension solely on the basis of spin-echo images (Figs. 11-56 and 11-57).[60] With increasing grade of the tumor, the tumor

margins tend to be more irregular. Glioblastoma multiforme, which is the most anaplastic form of astrocytoma, appears on long TR/TE images as a markedly hyperintense, irregularly bordered mass lesion. Also, with increasing tumor grade, there is progressive disruption of the blood-brain barrier, which, after intravenous administration of gadolinium, results in a progressively intense T1 shortening that is seen as increased signal intensity on short TR/TE images (Fig. 11-58). In pediatric patients, contrast enhancement can be seen in low-grade astrocytomas as well (Fig. 11-58). Oligodendrogliomas typically show hypointensity on short TR/TE images, with increased signal intensity on long TR/TE scans with signal void in areas of intratumoral calcification. Vasogenic peritumoral edema is infrequently seen, and enhancement following gadolinium-DTPA administration occurs in less than half of the cases.[143, 144]

VIEW IMAGE

FIGURE 11-57 Anaplastic astrocytoma of optic radiations. Axial T1-weighted image after administration of gadolinium shows an enhancing tumor mass involving the left optic radiations.

Meningiomas demonstrate signal characteristics that reflect the amount of calcification, vascularity, and interstitial fluid present within the mass.[151] In general, on short and long TR/TE images, meningiomas are isointense to hypointense to surrounding normal brain parenchyma (Fig. 11-59). As a result of the decreased conspicuity of meningiomas on MR imaging, detection is based on the displacement of normal structures of the neuraxis, including the white matter and vascular structures. On long TR/long TE images, surrounding edema, if present, helps to demarcate isointense meningiomas (Fig. 11-60). Intravenous administration of gadolinium delineates meningiomas much more clearly, because there is usually moderate to marked homogeneous enhancement.

Intracranial metastases display a variety of appearances on MR imaging. Characteristically, they appear on long TR/TE images as foci of increased signal intensity at the gray matter–white matter interface. Peritumoral edema is often present and may be difficult to distinguish from the tumor itself. Subtle differences in T1 and T2 relaxation time between the edema and the tumors may help in the differentiation. However, intravenous administration of gadolinium produces a clearer delineation (Fig. 11-61). The sensitivity for detection of single or multiple metastatic foci is increased with the use of gadolinium, thereby increasing

the certainty of the diagnosis of a metastatic cause (Fig. 11-50).[152] In metastatic lesions to the wall of the orbit, fat-suppressed, gadolinium-enhanced images are important in demonstrating the disease (Fig. 11-58). In fact, in cases in which multiplicity of lesions is uncertain with the standard dose of 1.0 mmole/kg gadolinium-DTPA, doubling or tripling the dose has been shown to increase the likelihood that additional lesions will be detected.[153–155]

Aggressive infectious disease processes affecting immunocompromised patients, such as those with HIV, may mimic the appearance of metastatic lesions (Figs. 11-62 and 11-63).

INTRODUCTION

Advances in the techniques of skull base surgery could not have been realized without the developments made in modern imaging. The precise preoperative mapping of a lesion and the demonstration of its relationship to vital neural and vascular structures have allowed surgeons to plan an approach maximizing the chance for resection while minimizing morbidity. Before the CT and MR imaging era, the extent of a tumor was determined at the time of surgery, and the morbidity of the extensive approaches needed to stage a tumor was considered unwarranted in many cases. Today the surgeon can differentiate a tumor that has a possibility of complete resection from one where cure is unlikely and removal would cause unacceptably high morbidity.

The field of skull base surgery is still evolving, with many questions yet to be answered. Certainly there is controversy regarding what procedures are reasonable and appropriate. Thus, although technically a skull base lesion can be accurately mapped and surgically extirpated, it remains for further analysis to determine when a treatment represents a significant advantage to a patient.

Surgeons from several disciplines combine their skills to achieve approaches that, though extensive, are designed to keep manipulation of the crucial and fragile neurovascular structures to a minimum. The tenet of these procedures is to move bone, not brain.

Other therapeutic options such as proton and neutron beams, gamma knife radiosurgery, and various other focused beam radiotherapeutic technologies all require precise imaging definition of tumor boundaries if the lesion is to be treated and crucial radiosensitive structures spared.

The skull base can be divided into several regions—anterior, central, and posterior or posterolateral. The anterior skull base consists of the floor of the anterior cranial fossa and the frontal sinus, including the roof of the ethmoid sinuses, nasal cavity, and orbits. This topic is covered in Chapters 1 to 7. The posterolateral skull base is the temporal bone, and this topic is covered in Chapters 19 to 26. The present chapter covers the central skull base.

The primary component of the central basicranium is the sphenoid bone, with a smaller contribution from the basiocciput. In addition, the soft tissues immediately contiguous to these bony structures form an integral part of the central skull base, and such structures as the cavernous sinus, the pterygopalatine fossa, and the soft tissues adjacent to the foramen ovale and the superior orbital fissure are also discussed in this chapter.

EMBRYOLOGY

The basicranium develops primarily from cartilage precursors, with a small component from membranous bone. A review of certain details of basicranium development is important in understanding some of the normal and abnormal imaging findings.

The primordial embryonic germ disk is composed of the two primary germ layers, the epiblast and the hypoblast. The epiblast, which will evolve into the ectoderm, develops from the floor of the amniotic cavity, while the hypoblast develops from the roof of the yolk sac. At the fourteenth day of embryonic life, demarcation at the anterior pole of the embryonic disk occurs, and a thickening, the prechordal plate, arises in the future midcephalic region. This prechordal plate prefaces the development of the oropharyngeal region and eventually gives rise to the endodermal layer of the oropharyngeal membrane. In the third week of gestation, the mesoderm proliferates in all directions between the two primary layers of the embryo, adding thickness to the embryonic disk.[1] These mesodermal cells are derived from the primitive streak at the caudal end of the ectodermal side of the embryo. Within the mesoderm, as a result of proliferation and differentiation, a more condensed core of cells, the notochord, stretches from the cranial end of the primitive streak toward the cranial end of the embryo and the prechordal plate. The notochord acts as an axial skeleton for the embryo and has a profound effect on the later development of the spine and the skull base. The notochord induces the formation of the neural plate in the overlying ectoderm (neural ectoderm).

Embryonic differentiation continues, and the formation of the primitive brain and cranial nerves begins. Only after the positions of these neural primordia are established does the skull base itself begin to form. Condensations of the mesenchyme along the notochord (paraxial mesoderm) and contributions from the neural crest progress from the occipital level cranially. This process forms the basal condensation referred to as the *desmocranium*. This mesenchymal blastema extends beyond the level of the tip of the notochord into the prechordal area. It is within this desmocranium that chondrification eventually occurs.[2, 3]

The notochord is contained within the basal condensation of mesoderm and maintains a close relationship to the developing brain and primitive pharynx (Fig. 12-1). The terminus of the notochord is close to the oropharyngeal membrane, separating the ectoderm of the stomatodeum from the endoderm of the primitive pharynx. The formation of Rathke's (hypophyseal) pouch, from the mucosa of the stomatodeum (ectoderm), is thought to be influenced by the notochord. This pouch, which will generate the anterior pituitary gland, passes through the basal mesoderm just cephalad to the tip of the notochord on the way to meet the diverticulum of the diencephalon, which will pass downward, forming the posterior pituitary.[4] Rathke's pouch and tract pass through the mesoderm before chondrification occurs.

Before reaching the prechordal plate, the notochord comes into contact with the endoderm of the primitive pharynx, close to the position of Rathke's pouch, but on the endodermal side of the oropharyngeal membrane. It is at this level that a small outpouching from the pharyngeal mucosa develops, apparently drawn cranially by the notochord. This is the pouch of Luschka, and its position is identified by the pharyngeal bursa, a midline evagination from the nasopharyngeal wall.[1]

Chondrification centers appear within the basal mesodermal condensation. Those centers forming around the distal notochord are the parachordal cartilages. The cartilages from the occipital sclerotomes (from the four occipital somites) are incorporated into the basal cartilaginous plate. Together the parachordal- and sclerotome-derived cartilages are responsible for the formation of the basiocciput.[6]

At about the same time and slightly more cephalad, the prechordal cartilage centers are forming.[3, 6] The hypophyseal ossification centers form on either side of the hypophysis and fuse together (Fig. 12-2), completely obliterating the remnant of Rathke's duct.[3] The fused hypophyseal cartilages represent the precursors of the basisphenoid, forming most of the body of that bone. The paired presphenoid (or trabecular) cartilages fuse to become the precursor of the most anterior part of the sphenoid bone (anterior to the tuberculum sella) and give rise to the mesethmoid cartilage. The mesethmoid cartilage, in turn, develops into the perpendicular plate of the ethmoid and the crista galli.

The sphenoid bone is completed by a group of more laterally placed cartilages also developing from the basal mesoderm.[6] The orbitosphenoid cartilage forms the lesser wing of the sphenoid and contributes to the optic foramen, and the alisphenoid cartilage center produces the medial part

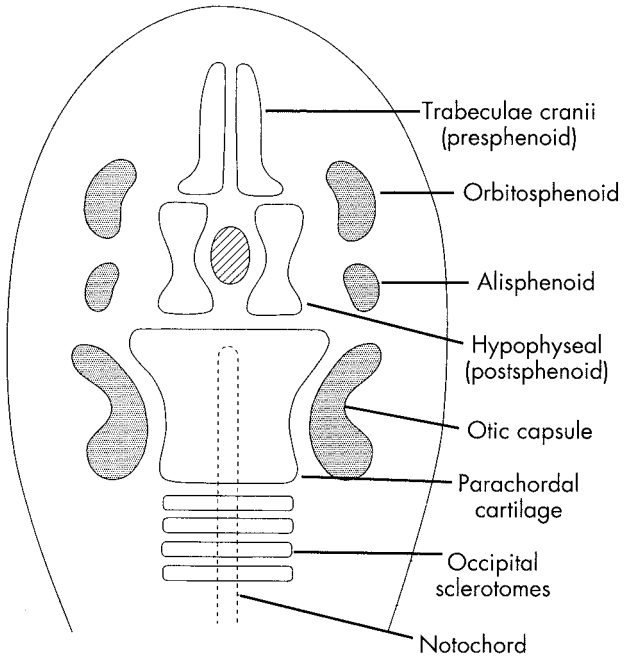
FIGURE 12-1 Midsagittal section depicting the course of the notochord. (From Batsakis JG. Soft tissue tumors of the head and neck: unusual forms. In: Tumors of the Head and Neck: Clinical and Pathological Considerations. 2nd ed. Baltimore: Williams & Wilkins, 1979; 353.)

of the greater sphenoid wing. The more lateral wing forms from condensed mesenchyme (intramembranous bone) rather than having a cartilaginous precursor.

The basiocciput and the various cartilage centers representing the sphenoid bone fuse into a cartilaginous continuum called the basal cartilaginous plate. The various foramina of the final basicranium are present within this primitive cartilaginous formation because the nerves and vessels have developed before chondrification begins and the cartilage is forced to develop around them. The bilateral otic capsule chondrifications also fuse to the parachordal cartilages and thus are joined with the basal plate.

Ossification centers now form within the cartilaginous precursor centers. This mechanism produces the presphenoid and postsphenoid as well as the lesser and greater wings. The pterygoid plates and portions of the greater wings form by intramembranous ossification. The small hamulus of the pterygoid develops endochondrally from a small chondroid center.

As ossification progresses, most of the cartilage between the centers is obliterated. Remaining cartilage can be found in various synchondroses, which persist into adult life. The most prominent ones are in the foramen lacerum and petroclival junction. The presphenoid and postsphenoid bones usually fuse by birth, but occasionally the separation persists in the newborn.[7] The bones of Bertin are two small, paired ossification centers that quickly fuse with the anterior sphenoid. It is here that pneumatization of the sphenoid bone begins. Thus, the initial air cells are formed in the



VIEW IMAGE

FIGURE 12-2 Diagram of the chondrification centers within the basal mesodermal condensation. The hypophyseal centers form on either side of the hypophysis and eventually fuse to form the sella and obliterate the pharyngohypophyseal canal. The postsphenoid is formed from these cartilage centers. The presphenoid forms more anteriorly. The orbitosphenoid and alisphenoid will contribute to the greater and lesser wings respectively.

presphenoid and progress into the more posterior and lateral ossification centers.

ANATOMY

The sphenoid bone is rightfully the focus of any discussion of the central skull base (Fig. 12-3).[8–11] The anterior basiocciput, articulating with the posterior inferior aspect of the sphenoid bone, also makes an important contribution to the central skull base. Equally crucial to imaging evaluation of the central skull base is an understanding of the contiguous soft tissues.

Bone

The sphenoid bone consists of a body, the greater and lesser wings, and the pterygoid processes (Fig. 12-4). The term *sphenoid* is derived from the Greek word for ''wedge,'' perhaps referring to its shape or its position between the basiocciput and the anterior skull base. The bone itself has been likened to the appearance of a diving horned owl when viewed from the anterior.

The central part of the sphenoid bone is a block-like structure variably hollowed out by the sphenoid sinus and bordered by many perforations, allowing passage of nerves and vessels. The great wings of the sphenoid sweep laterally, reaching and contributing to the lateral surface of the calvarium, just anterior to the squamous part of the temporal bone. Here the sphenoid bone articulates with the frontal bone, temporal bone, and parietal bone. The lesser wings are more medial in position and form the superior margin of the superior orbital fissure. The anterior clinoid is the posterior margin of the lesser wing. The pterygoid processes, with medial and lateral plates, drop inferiorly from the junction of the body and the greater wing.

Although much of the surface anatomy of the sphenoid bone, such as the sella turcica, the anterior and posterior clinoid processes, and the pterygoid plates, is familiar to the reader, other, slightly more obscure landmarks may be helpful in analyzing some of the imaging findings.

The superior surface of the sphenoid bone forms part of the floor of the anterior cranial fossa (Fig. 12-4B). Just posterior to the cribriform plate of the ethmoid bone, the ethmoid process of the sphenoid bone makes up the most anterior part of the planum sphenoidale. The planum is a flat region separating the cribriform area anteriorly from the chiasmatic sulcus, or groove, posteriorly. The planum is contiguous laterally with the flat superior surface of each lesser sphenoid wing.

The chiasmatic sulcus is a small, linear, transversely oriented depression just posterior to the planum (Fig. 12-4B-D). The anterior rim of the sulcus is referred to as the limbus and represents the most posterior ossification of the presphenoid ossification center. The posterior rim of the chiasmatic sulcus is the tuberculum, which represents the anterior ossification of the postsphenoid ossification center. The sulcus itself is thus the region that remains between these two ossification centers and is not the expected location of the optic chiasm, as its name implies. The turberculum separates the sulcus from the sella turcica. The optic canals enter the intracranial compartment at the level of the lateral margins of the chiasmatic sulcus.

The dorsum sella is a roughly rectangular plate of bone forming the posterior wall of the sella. The posterior surface of the dorsum is continuous with the posterior surface of the body of the sphenoid and basiocciput. This sloping surface is called the clivus.

On each side, the sphenoid bone is separated from the petrous apex of the temporal bone by the large foramen lacerum. The foramen lacerum is continuous with the smaller, more posterior petrooccipital fissure (petroclival synchondrosis). Both of these are filled with plates of cartilage.

The carotid artery exits the tip of the petrous apex and passes along the lateral aspect of the sphenoid body, causing a groove that reaches almost to the anterior clinoid process. This groove may cause an indentation on the lateral wall of the sphenoid sinus when viewed from within the sinus (Fig. 12-5).

The inferior surface of the sphenoid is very irregular, with many grooves and spurs (Fig. 12-4E,F). The pterygoid processes have already been mentioned. The free margin of the upper posterior edge of the medial pterygoid plate splits to form a shallow groove called the scaphoid fossa. The fossa extends posterolaterally toward the spine of the sphenoid. The tensor veli palatini muscle attaches to the scaphoid fossa and to the sphenoid spine. The sphenomandibular ligament also attaches to this spine.

More medially, the body of the sphenoid forms the roof of the nasopharynx. The rostrum of the sphenoid is in the midline and articulates with the vomer. More superiorly, on the anterior surface of the body, the midline ethmoid crest of the sphenoid articulates with the perpendicular plate of the ethmoid. The orifices to the sphenoid sinus are just lateral to this crest.

An understanding of the various perforations, foramina, and fissures of the sphenoid bone can be achieved best by studying cross-sectional images along with the pictures of specimens (Figs. 12-6 to 12-9).

In the axial plane (Fig. 12-7), the optic foramina (canals) converge toward the sella and optic chiasm and are almost perpendicular to one another. The cross-sectional shape of the optic canal changes from its intracranial to its extracranial margins. The intracranial margin of each optic canal has a slightly oval shape with the long axis horizontal. The midportion of the canal is circular and the intraorbital margin of the canal has an oval shape with the long axis vertical. The superior orbital fissure is a curving cleft when viewed from the front. When viewed in the axial plane, the fissure is directed toward the anterior cavernous sinus rather than toward the region of the sella. In the majority of cases a small amount of the orbital fat extends through the fissure to abut the cavernous sinus.

Just caudal to the superior orbital fissure, the foramen rotundum and the Vidian canal (pterygoid canal) pass from posterior to anterior through the skull base. The foramen rotundum is shorter, wider, and fairly straight, and it is found immediately inferior to the superior orbital fissure. In some individuals the foramen is extremely short, appearing only as a gap in the bone on axial images. The foramen rotundum passes from the cavernous sinus region to the pterygopal-

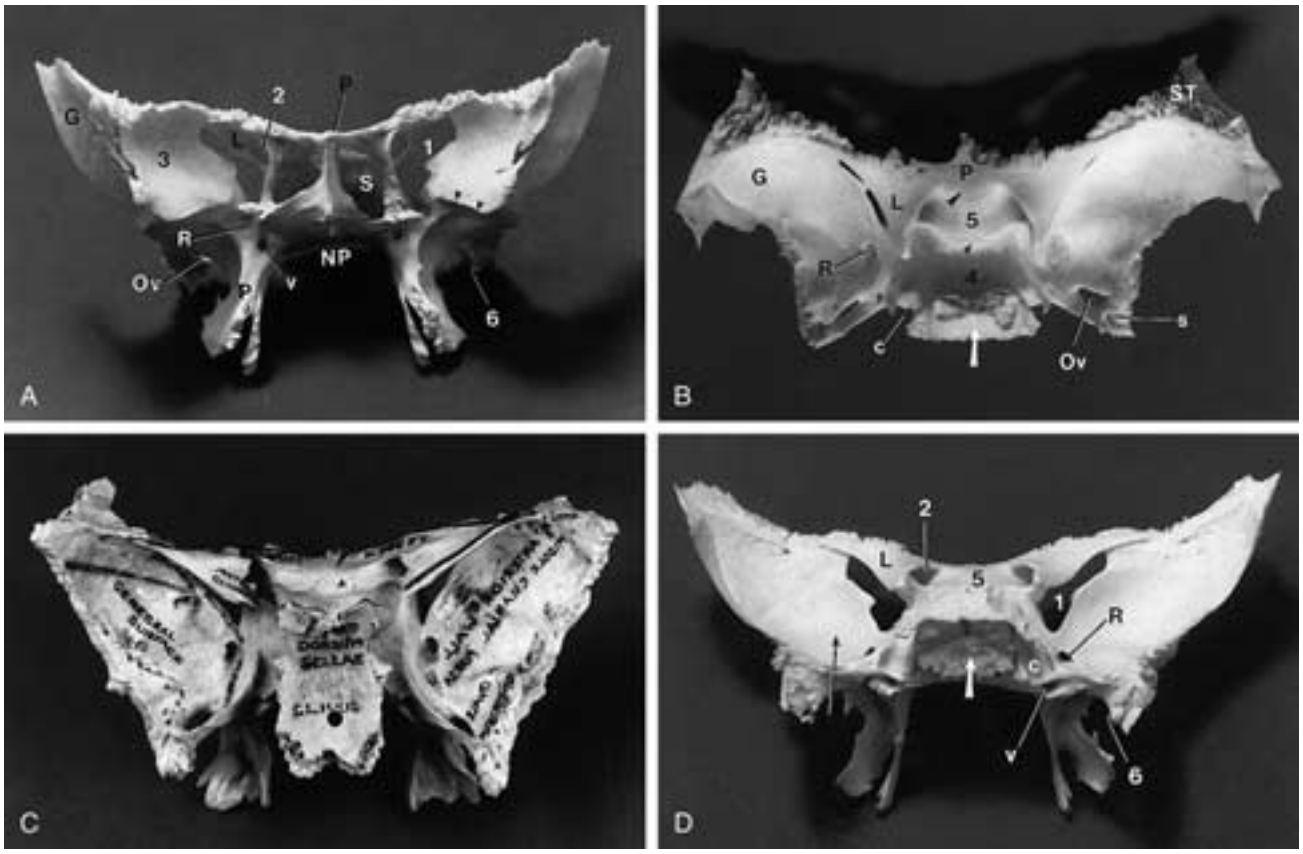
atine fossa (Fig. 12-7D) and enters the fossa at the level of the inferior orbital fissure. The inferior orbital fissure separates the greater wing of the sphenoid from the more anteriorly located orbital floor.

The Vidian canal (pterygoid canal) (Fig. 12-7F) has its ventral margin more medial than its dorsal end, and its dorsal aspect points toward the carotid canal (petrous portion) rather than toward the cavernous sinus, as does the foramen rotundum. The Vidian canal is more inferior, slightly medial, longer, and narrower than the foramen rotundum. The anterior opening of the Vidian canal flairs (Vidian's trumpet) into the pterygopalatine fossa at the level of the sphenopalatine foramen. This foramen communicates between the pterygopalatine fossa and the posterior nasal cavity and nasopharynx.

The foramina ovale and spinosum (Fig. 12-7F) also extend through the sphenoid bone at the junction of the body and greater wing. They transmit the third division of the trigeminal nerve and the middle meningeal artery, respectively. The foramen ovale is anterior and medial to the foramen spinosum. The foramen ovale angles somewhat anteriorly and slightly laterally toward its extracranial opening. The foramen of Vesalius (emissary sphenoidal foramen) is an inconstant channel that passes anterior and slightly medial to the foramen ovale, carrying a small vein from the cavernous sinus. Other canals occasionally can be seen passing close to the foramen ovale through the medial greater wing of the sphenoid and root of the pterygoid. These are believed to carry venous connections from the cavernous sinus to the pterygoid plexus.[12]

The same anatomic landmarks also can be appreciated in the coronal plane (Figs. 12-8 and 12-9). Now the foramen



VIEW IMAGE

The scaphoid groove (*arrowheads*) is the attachment of the tensor veli palatini. The foramen ovale and foramen spinosum can be identified. **F**, View from inferiorly shows the rostrum (*R*) of the sphenoid, the sphenoid crest (*7*), the nasopharyngeal surface (*NP*), the greater wing of the sphenoid (*G*), and the pterygoid process (P). The letter P is on the lateral plate. The dotted line curves onto the medial plate indicated by the open arrow. The scaphoid fossa (*small arrowheads*) is the origin of the tensor veli palatini. The foramen ovale (*Ov*) and foramen spinosum (unlabeled) are partially obscured by the spine (*6*) of the sphenoid. **G**, Lateral view of the skull shows the pterygoid process (*P*) and the lateral surface of the greater wing (*G*) of the sphenoid. The large arrowhead indicates the pterygopalatine fossa. The small arrowheads are seen along the suture between the greater wing of the sphenoid and the squamosa of the temporal bone. The arrow indicates the glenoid fossa of the temporomandibular joint. *6*, Spine of the sphenoid. **H**, Lateral view of the sphenoid bone disarticulated. (Courtesy Dr. Lewis E. Etter collection.) Lateral view shows the greater wing of the sphenoid (*G*) and the pterygoid plates. More centrally, the posterior clinoid (*arrow*) is seen at the top of the dorsum sella. *Arrowhead*, Anterior clinoid; *S*, sella.

rotundum and the Vidian canal are seen in cross section, while the foramina ovale and spinosum are seen in longitudinal section. More posteriorly, Meckel's cave and the cavernous sinus structures are seen well in the coronal cross section.

At imaging, the normal appearance of the sphenoid bone depends on the degree of sinus development (Figs. 12-6 and 12-10) and the type of marrow present in the bone. The medullary space of the infant is predominantly red marrow. This is gradually replaced by fat of inactive yellow marrow.[13] This change begins in early childhood and progresses into adolescence. Usually by the late teens, the sphenoid medullary cavity is completely replaced by fat, giving a characteristic appearance at CT and MR imaging. For example, the medullary space of the basicranium in most infants less than 1 year of age has a uniformly low signal intensity on T1-weighted images. Areas of high signal intensity, representing fat, rapidly appear, and by the age of

Copyright © 2003, Mosby, Inc. All rights reserved.

7, some fatty marrow is present in virtually all people. Frequently, there are patches of both high and low signal intensity, giving an irregular MR pattern.[14, 15] By the age of 15, a uniformly fatty marrow with high signal intensity on T1-weighted images is present in most people, although some red marrow with lower T1-weighted signal intensity can persist into adulthood.

In the adult, fat is usually evenly distributed throughout the medullary space, interspersed around the remaining trabeculae. Some areas may be devoid of trabeculae, suggesting a cystic cavity such as a mucocele. However, the typical MR imaging signal intensities of fat or the typically low CT density allow the radiologist to make this differentiation (Figs. 12-11 and 12-12).

The sphenooccipital synchondrosis represents the junction of the occipital and sphenoid bones. This often can be seen on sagittal MR imaging or even on plain films in infants. It fuses in most children by the age of 8 years. The synchondrosis is a linear cleft that passes from the intracranial clivus to the pharyngeal surface of the basicranium. Sometimes the synchondrosis between the anterior and posterior ossification centers of the sphenoid can be seen in the infant (Fig. 12-13). This more ventral synchondrosis passes from the tuberculum or the anterior wall of the sella to the pharyngeal side of the sphenoid.[16, 17] This structure is anterior to the course of Rathke's pouch and tract and should not be confused with that embryonic structure.

Sphenoid sinus air cell development begins at birth. Initial air cell development is in the presphenoid region anteriorly, and further enlargement proceeds posteriorly to invade the basisphenoid.[18] Sinus development is slow for the first several years and then accelerates, so that by about the age of 7 or 8 years, the dorsal margin of the sinus has reached the anterior sella turcica.[13, 18] Expansion then continues in all directions, with sinus aeration frequently extending into the dorsum sella and anterior clinoids. Large sinuses can appear to extend down well into the basiocciput. Laterally, the air cells can extend between the foramen rotundum and the Vidian canal into the root of the pterygoid or even into the greater wing. If there is development of these lateral air cells, the space between the foramen rotundum and the Vidian canal is wider than if these air cells are not present. This increased separation should not be considered pathologic.[19]

The position of the septations within the sphenoid sinus varies considerably. Many of these septations pass from anterior to posterior. They can attach to the roof of the sphenoid (the floor of the sella). Some can curve laterally to attach to the bony wall separating the carotid artery from the sphenoid sinus. In this case, a fracture at the carotid groove is of concern if the septation is manipulated at surgery. The foramen rotundum may project into the lower lateral sinus wall, usually as a curved ridge. The Vidian canal may be in the sphenoid bone below the floor of the sphenoid sinus or it may be on a septum just above the sinus floor. A final normal variation of the architecture of the sphenoid bone is the formation of arachnoid granulations along the inner surface of the greater wing of the sphenoid, where the bone forms the anterior wall of the middle cranial fossa (Fig. 12-14). These ''pits'' can be visualized frequently on CT and should not be considered pathologic. In cases of nontraumatic CSF leaks these pits have been implicated as a causal factor. It has been suggested that the thin bone separating one of these pits from another may break, creating a communication with an air cell in the greater wing of the sphenoid.[20]

The occipital bone forms the margin of the foramen magnum and extends up to meet the basisphenoid at the sphenooccipital synchondrosis (Fig. 12-15). This synchondrosis is usually about one third up the length of the posterior surface of the clivus. It is the basilar part of the occipital bone that forms the region anterior to the foramen magnum. The lateral part of the occipital bone forms the lateral margin of the foramen magnum and includes the large occipital condyles, prominent landmarks on the caudal aspect of the skull. The jugular process of the occipital bone juts laterally and has a rounded prominence called the jugular tubercle along its superior margin. The hypoglossal canal passes just above the occipital condyle and just below the jugular tubercle. Posterior to the condyle is the condyloid canal, which enters this fossa carrying an emissary vein.[21, 22]

Note the small recess (*arrowhead*) between the optic canal impression (*O*) and the bulge from the carotid artery (*black arrow*). The white arrow indicates the impression of the sella.

Bordering Soft Tissues

The evaluation of the soft tissues that border the skull base can be crucial in the analysis of disease. Just as lesions arising in the skull base itself can expand into these areas, lesions arising above or below the skull base can invade it. Importantly, the imaging demonstration of normal soft tissues between the skull base and a tumor is reassuring evidence that the skull base has not been invaded.

Extracranial Soft Tissues

The extracranial openings of the fissures and foramina of the skull base are bordered by soft tissues primarily

FIGURE 12-6 **A**, Midline sagittal T1-weighted MR image of the skull base in an adult. *PT*, Pituitary within the sella turcica; *SS*, sphenoid sinus; *C*, clivus. **B**, Midline sagittal T1-weighted MR image of the skull base in a child. *DS*, Dorsum sellae; *PT*, pituitary within the sella turcica; *BS*, basisphenoid; *SS*, sphenooccipital synchondrosis; *BO*, basiocciput.

containing fat, and just as in the remainder of the head and neck, this fat is important in the imaging analysis of the skull base. Because fat has a very characteristic appearance on CT and MR imaging, excellent contrast is afforded between normal tissue and most lesions, particularly cellular tumors. Thus, for instance, as a tumor approaches the base of the skull, the progressive obliteration of the fat planes allows detection of tumor infiltration.

The optic canal and the superior orbital fissure open into the orbit (Fig. 12-7), and although the optic nerve and the extraocular muscles occupy space in the orbital apex, there is still sufficient fat to allow detection of most lesions. Indeed, as mentioned, the orbital fat normally protrudes slightly through the superior orbital fissure into the region of the anterior cavernous sinus.

The foramen rotundum and the Vidian canal open into the pterygopalatine fossa. The fossa is filled almost entirely by fat (Figs. 12-7 and 12-8). This narrow cleft (Fig. 12-4G) behind the medial posterior wall of the maxillary sinus takes its name from the bones that make up the walls of this space. The pterygoid process of the sphenoid forms the posterior wall (Fig. 12-16), while the superiorly projecting orbital

Copyright © 2003, Mosby, Inc. All rights reserved.

process of the palatine bone makes up the anterior wall. The pterygopalatine fossa connects with five spaces: the central skull base and middle cranial fossa via the Vidian canal and the foramen rotundum, the orbit via the inferior orbital fissure, the infratemporal fossa via the retromaxillary or pterygomaxillary fissure, the nasal cavity via the sphenopalatine foramen, and the oral cavity via the pterygopalatine canals in which run the greater and lesser palatine nerves (Figs. 12-17 to 12-19). In addition, the second division of the trigeminal nerve branches in the pterygopalatine fossa before carrying sensory innervation to the face and to the mucosa of the palate (Fig. 12-17), and these nerves can be the pathway of tumor spread. Thus, the pterygopalatine fossa is an important landmark in staging of head and neck tumors.

VIEW IMAGE

Within the fat of the pterygopalatine fossa are the branches of the maxillary nerve, the pterygopalatine ganglion, and small vessels. Though a small amount of soft tissue can be identified in the fossa, the predominant imaging finding is fat, which serves as an important imaging landmark when evaluating potential tumor spread.

The foramen ovale opens into the masticator space below the skull base. As the third division of the trigeminal nerve exits the skull via this foramen, the nerve emerges into fat along the medial margin of the lateral pterygoid muscle.[23] The nerve passes just superficial (lateral) to the sphenomandibular ligament and the fusion of fascial layers that form the medial boundary of the masticator space. The tensor veli palatini muscle takes its origin along a line from the scaphoid fossa to the spine of the sphenoid bone. This small, thin muscle plays an important role in the fascial organization of the parapharyngeal spaces.

Intracranial Soft Tissues

Intracranially, most of the foramina converge to the region of the cavernous sinus and Meckel's cave (Figs. 12-7 and 12-8). The optic canals open into the suprasellar cistern. The cavernous sinus is a venous sinusoid structure situated between the layers of the dura, bordering the pituitary fossa

Copyright © 2003, Mosby, Inc. All rights reserved.

and the body of the sphenoid (Fig. 12-20). The cavernous sinus forms much of the medial wall of the middle cranial fossa.

The dural organization at Meckel's cave and the cavernous sinus is derived from the dural coverings of the contiguous inner surfaces of the skull. Two layers can be appreciated. The outer (peripheral) layer of the dura follows the bone of the skull base. The inner layer is reflected upward, forming the lateral wall of Meckel's cave and the cavernous sinus before attaching to the clinoids. This inner layer of dura has a secondary reflection that passes anteriorly from posteriorly, forming Meckel's cave. This cave can be thought of as a very loose root sleeve around the trigeminal nerve and ganglion.

The cavernous sinus is located at the superomedial aspect of Meckel's cave and extends anteriorly from that point. The cavernous sinus contains several nerves. The ophthalmic division of the trigeminal nerve passes into the cavernous sinus on the way to the superior orbital fissure. The maxillary division of the trigeminal nerve has a shorter course within the cavernous sinus before entering the foramen rotundum. The third division of the trigeminal nerve exits almost directly from Meckel's cave and does not truly enter the cavernous sinus. The semilunar or Gasserian ganglion, the convergence of the divisions of the nerve, lies along the lateral wall of Meckel's cave. The oculomotor, trochlear, and abducens nerves traverse the entire anteroposterior length of the cavernous sinus before exiting the skull at the superior orbital fissure.

The internal carotid artery also traverses the cavernous sinus. The artery curves superiorly immediately after exiting the petrous carotid canal. This brings the artery into the

cavernous sinus between Meckel's cave and the lateral wall of the sphenoid sinus. The artery then curves anteriorly, making a short bend before passing through the dura just below the optic nerve.

IMAGING

Plain film investigation of the skull base has given way to CT and MR imaging. However, the skull base is ever present on any projectional image of the skull or of the sinuses. Indeed, a major factor in the development of the different views used in plain film radiography of the temporal bone and sinuses was an attempt to project the area of interest away from the confusing densities of the skull base. Although plain films are seldom used when skull base pathology is suspected, skull base problems can mimic various types of facial and sinus pathology. Thus, familiarity with the normal projectional anatomy is appropriate. This is discussed in Chapter 2.

CT can be performed in the axial and coronal planes. Other slice orientations and three-dimensional (3D) images can be reformatted. The advent of multidetector scanners with slice thicknesses approaching the dimensions of the pixel allows high-quality reformatting in any plane. This imaging advance is lessening, and in many cases eliminating, the need to perform direct coronal imaging. In turn, this eliminates the imaging-degrading beam-hardening artifacts from dental restorations so common on direct coronal CT. A slice thickness of no greater than 3 mm should be used, with thinner scans used to answer specific diagnostic questions regarding some of the smaller skull base foramina. The optimal slice thickness may change as more experience with the multidetector scanners is gathered.

Contrast is used whenever the cavernous sinus is examined or intracranial tumor is suspected. Bone algorithms are utilized to optimally visualize the thin cortices around the various foramina, and soft-tissue algorithms allow evaluation of the soft tissues adjacent to the skull base.

Although MR imaging can be performed in any plane, the routine examination should include the sagittal, axial, and coronal views, particularly in tumor cases. Gadolinium is used routinely to evaluate the cavernous sinus and potential intracranial tumor. Because some enhancing tumors can be as bright as fat, the interface between the lesion and the fat planes below the skull base can be lost unless either a precontrast sequence is obtained or fat suppression is used. One must be careful when fat suppression is employed, because the interface between the sphenoid sinus air and its wall often results in a significant susceptibility effect. This ''blooming'' can void the signal from important structures such as the cavernous sinus and the foramen rotundum (Fig. 12-21). The radiologist must be confident that the foramen

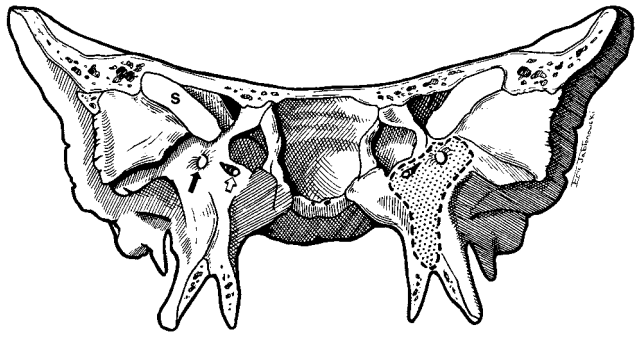
has been adequately visualized either with or without fat suppression. Frequently, a subtle vascular plexus can be identified around the nerve within the foramen. Because of these plexes, symmetric slight enhancement of the cranial nerves as they exit the skull base may be seen routinely. It is only when there is asymmetric enhancement that pathology should be suspected. On the other hand, the Gasserian ganglion has sparse vascularity, and thus this ganglion should not enhance routinely on contrast MR sequences. If enhancement is seen within a Gasserian ganglion, it should be considered pathologic.

Fat suppression is often used with the newer fast spin-echo, T2-weighted sequences. On conventional spin-echo images, fat has a high T1-weighted and a low T2-weighted signal intensity. However, on fast spin-echo imaging, fat has a high signal intensity on both T1-weighted and T2-weighted images. Thus, on the T2-weighted fast spin-echo images, fat suppression can give an imaging appearance similar to that of the conventional spin-echo images. Again, the susceptibility effect of air and tissue can present imaging problems.

If the areas of the central skull base, cavernous sinuses, and sphenoid sinus are to be evaluated, a suggested protocol for the routine case includes T1-weighted sequences with and without gadolinium and T2-weighted scans; 3-mm-thick sections are used for the T1-weighted sequences, and 4- to 5-mm-thick sections are used for the T2-weighted scans.



VIEW IMAGE

VIEW IMAGE

FIGURE 12-21 Very large benign tumor of the parotid gland extending through the floor of the middle cranial fossa. **A**, Coronal T1-weighted MR image with fat suppression after gadolinium administration. The tumor (*T*) can be readily visualized. The sphenoid sinus (*S*) is filled with air. The air causes ''blooming'' of the sinus laterally (*arrowhead*), obscuring the lower cavernous sinus in the region of the foramen ovale. This is due to the susceptibility effect. **B**, Without fat suppression, on a T1-weighted image after gadolinium administration, the lateral margin of the sphenoid sinus (*arrowhead*) is much better seen, as is the lower cavernous sinus. A small amount of tumor obscured with the previous image is well seen (*arrowhead*) protruding into the middle cranial fossa. *T*, Tumor.

Usually, high resolution (high matrix, low field of view) is included in the plane most likely to visualize a key structure.

In cases where a CSF leak is of concern or determination of the precise margin of the brain must be demonstrated relative to a defect in the skull base, either a high-resolution, T2-weighted sequence or a true inversion recovery sequence may be added.

NONNEOPLASTIC DISORDERS

Congenital and Developmental Anomalies

There are many normal variations in the sphenoid bone, most notably the degree of sinus pneumatization and the rate and final extent of replacement of red marrow by fatty yellow marrow. These variations were discussed previously under normal imaging appearance of the sphenoid bone.

Congenital or developmental abnormalities may represent either actual developmental problems of the sphenoid bone itself or reactions of the sphenoid bone to problems occurring elsewhere. For example, a cephalocele can occur through an actual deficiency in the sphenoid bone, whereas the distortion of the greater wing of the sphenoid that occurs in a patient with premature closure of the coronal suture represents an attempt of a normal sphenoid bone to compensate for an abnormality elsewhere. Although various dysplasias could be included in this section, they are discussed in this chapter and in Chapter 24.

Cephaloceles

A cephalocele is a protrusion of intracranial contents through a defect in the skull. The dura may be thinned or actually dehiscent. If the protrusion is composed of only the meninges and the subarachnoid space containing CSF, the term meningocele is used. If the sac also contains brain, the appropriate term is encephalocele. Though meningoceles can occur anywhere in the skull, most are found in the midline.

Cephaloceles occur sporadically, approximately once in 4000 births.[24] Most involve the cranial vault, with only about 20% of encephaloceles involving the anterior or central skull base. Of these, most are anterior in location (sincipital encephaloceles) and are considered to represent failures of neural tube fusion at the level of the anterior neuropore. A different mechanism must be postulated for those cephaloceles that pass through the region of the sphenoid.

Some authors have attributed the passage of encephaloceles through the sphenoid bone to persistence of the craniopharyngeal canal.[25] However, other authors question this concept, indicating that the adenohypophysis ascends too early, well before there is significant organization of the developing basicranium.[26] These authors have attributed the small canal occasionally identified traversing the sphenoid, between its pharyngeal surface and the pituitary fossa, to small blood vessels present in the embryo.

A second proposed theory is that these basal cephaloceles are herniations through defects related to problems with

Copyright © 2003, Mosby, Inc. All rights reserved.

fusion of the many ossification centers participating in formation of the skull base. These authors indicate that the route taken by most of these encephaloceles through the sphenoid bone conforms most closely to the synchondrosis between the presphenoid and postsphenoid ossification centers. This course passes from the region of either the tuberculum sella or the anterior wall of the sella, anteriorly and inferiorly toward the pharynx (Fig. 12-13). This theory also explains the occurrence of lateral basal encephaloceles that pass between the nonunited ossification centers of the postsphenoid and alisphenoid, precursors of the body and greater sphenoid wing, respectively.[27] Some encephaloceles appear to pass directly through the more lateral greater wing of the sphenoid.[28] This structure is formed by membranous bone, and perhaps in these cases a defect in formation of the bone itself can be implicated. This type of defect is seen in neurofibromatosis but can occur as an isolated abnormality as well.

The outer covering of the cephalocele is determined by the tissues found adjacent to the defect.[29] This may be a derivative of skin or mucous membrane, depending on the location. Most of the basal encephaloceles pass into the nose or nasopharynx and are covered by mucosa. By comparison, those cephaloceles that pass laterally into the infratemporal fossa have a fibrous wall derived from the dura and from the myofascial elements found in that location. Basal encephaloceles have been categorized depending on their point of passage through the skull base and on their final destination.[25, 28, 30] One system includes the following types: (1) transethmoidal, (2) sphenoethmoidal, (3) sphenorbital, (4) transsphenoidal, and (5) sphenomaxillary. Perhaps it is easiest to group the abnormalities into midline basal and lateral basal encephaloceles.

The transsphenoidal, sphenoethmoidal, and transethmoidal varieties occur in the midline (Figs. 12-22 and 12-23). The sphenoethmoidal passes through the sphenoethmoid area into the posterior nasal cavity or anterior nasopharynx. If the abnormality extends into the sphenoid sinus but does not perforate the floor to reach the nasopharynx, the term transsphenoidal is used. As the name suggests, transethmoidal encephaloceles are more anterior in location, passing through the anterior ethmoid and cribriform plate into the more anterior sinonasal system. Another term that may be encountered is sphenopharyngeal encephalocele. This type extends through the sphenoethmoid region into the nasopharynx and can be included in the sphenoethmoid group.

Lateral basal encephaloceles include the sphenorbital and sphenomaxillary types. The sphenorbital encephalocele passes through the region of the superior orbital fissure into the orbit, causing proptosis, often pulsatile proptosis. This type is commonly associated with neurofibromatosis and is considered to be an expression of the mesodermal component of this disease (Fig. 12-24) because the greater wing and often the lesser wing of the sphenoid do not develop normally and have defective ossification.[31] This gives the characteristic plain film appearance of a bare or empty orbit (Fig. 12-25).

The sphenomaxillary encephalocele is extremely rare, and few documented examples exist (Fig. 12-26).[27, 32–35] These lesions may squeeze into the pterygopalatine fossa and then pass laterally into the infratemporal fossa, presenting as a mass in the cheek. The more lateral transalar encephaloceles do not fit well into either the sphenomaxillary or sphenorbital groups, but they certainly could be included in the category of lateral basal encephalocele.

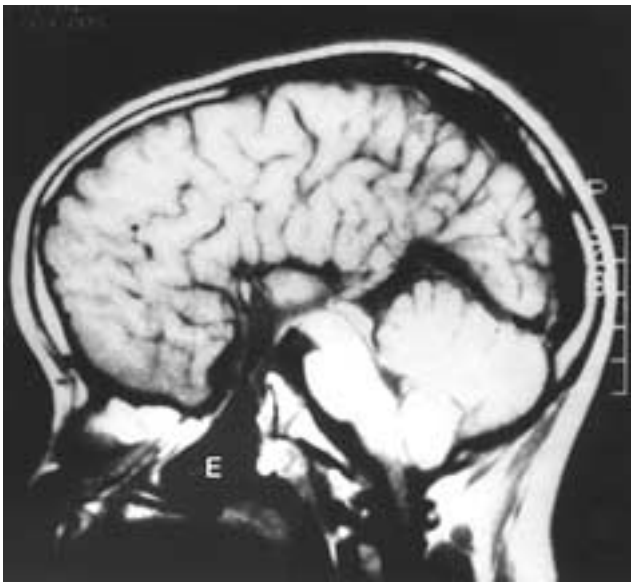

FIGURE 12-22 Sphenoethmoidal encephalocele. Sagittal T1-weighted MR image shows the encephalocele (*E*) extending into the nasal cavity, resting on the hard palate. The connection can be followed through the anterior sella and anterior sphenoid. This would be the approximate position of the fusion line of pre- and postsphenoids. The cystic abnormality did contain brain tissue along the wall and therefore qualifies as an encephalocele.

VIEW IMAGE

Patients with basal encephaloceles frequently have other anomalies. Most involve the midface. Hypertelorism is common, particularly with the more anterior varieties of encephaloceles. Cleft lip and cleft palate are also frequently associated findings, as is agenesis of the corpus callosum.[36]

The clinical presentation of cephaloceles varies; a submucosal mass in the nasal cavity or nasopharynx may present with airway obstruction, CSF leaks or recurrent meningitis may result from the weakened barrier between the sinonasal tract and the intracranial contents, and symptoms relating to involved central nervous system components can also be found. Herniations of the optic pathways, hypothalamus, or portions of the frontal lobes occur with midline defects. When the temporal lobe protrudes into the defect, the patient may present with seizures.

When imaging cephaloceles, the bony defect is better seen on CT than MR imaging. Usually there is a smooth cortical margin surrounding the tract, and the soft-tissue mass is identified passing into the extracranial region. Three-dimensional reformatted images can be used to show the relationship of the defect to the remaining basicranium.

Although MR imaging does not show the bony anatomy quite as well as CT, it better characterizes the contents of the herniated soft tissues and any related intracranial abnormalities.

Altered Ossification

If the presphenoid ossification extends further dorsally than normal, the postsphenoid ossification bone is corre-

Copyright © 2003, Mosby, Inc. All rights reserved.

spondingly shorter than normal. This results in the limbus, chiasmatic sulcus, and tuberculum being vertically oriented, elongating the anterior wall of the sella turcica. The resulting sella configuration is J-shaped, and this type of altered ossification occurs in such conditions as Turner's syndrome, achondroplasia, and the mucopolysaccharidoses. This represents a developmental J-shaped sella rather than one that occurs due to erosion of the dorsum sellae by a hypothalamic mass.

Vascular Variants

There are many minor variations of the arterial and venous vessels in and around the central skull base. Many represent normal variations of origin or course. The course of the carotid artery in the region of the cavernous sinus is quite constant; however, the artery can curve more medially than normal, pushing into the sphenoid sinus. The lateral sinus wall bone covering the medial aspect of the artery can be dehiscent, putting the vessel at risk during surgical procedures involving the sphenoid sinus (Fig. 12-27). Even when the artery is in a normal position, the bone separating the carotid artery from the sphenoid sinus may be quite thin. If a septation of the sphenoid sinus curves to attach to this thin bone, there is concern that manipulation of the septation may fracture the bony wall, injuring the vessel.

The persistent trigeminal artery is a large arterial variant that represents an abnormal persistent communication between the carotid artery and the basilar circulation (Figs. 12-28 and 12-29). This vessel is seen easily on arteriography and may be large enough to be visualized on CT or MR imaging. The vessel passes from the proximal cavernous carotid artery posteriorly to connect with the basilar artery.

The effect of the variations of venous passages through the skull base is thought to account for at least some of the

FIGURE 12-23 An 8-year-old child presenting with recurrent bouts of meningitis. Basal encephalocele (transsphenoid). Whether this passes through the synchondrosis or through a persistent cranial pharyngeal canal is controversial. **A**, Plain film of the skull, submental vertex view. VIEW IMAGE

channels and foramina seen in the region of the foramen ovale. The best known of these variable channels is the foramen of Vesalius just anterior and medial to the foramen ovale. Ginsberg et al. used the term lateral rotundal canal to describe a channel passing vertically just lateral to the foramen rotundum.[12] They are thought to be channels connecting the cavernous sinus with the pterygoid plexus.

Developmental Changes Caused by Extrinsic Factors

The skull base develops in a complex environment, and the growth patterns of the sphenoid bone are modified by abnormalities occurring in the adjacent region. Craniosynostosis, or premature closure of a suture, prevents normal growth of a particular segment of the skull. The remaining

Copyright © 2003, Mosby, Inc. All rights reserved.

bones of the skull also become distorted as they attempt to make room for the growing brain (Fig. 12-30). The skull base has a limited ability to respond in these situations, but some characteristic changes are seen. Thus, coronal synostosis limits the ability of the calvarium to add to its length, yielding a brachiocephalic skull that is foreshortened from front to back and may be larger than normal in its vertical dimension. The greater wing of the sphenoid bone displaces anteriorly, as does the petrous bone, and the orbit is pushed forward and is somewhat shortened. These changes can occur on one or both sides, depending on the extent of sutural involvement.

Abnormalities in the contiguous soft tissues and CSF spaces also can have an effect on the shape, thickness, and position of the sphenoid bone. Primary or congenital arachnoid cysts are abnormal arachnoid or collagen-lined cavities that characteristically do not communicate with the ventricular system. They account for 1% of intracranial space-occupying lesions and usually appear in the first five decades of life.[37, 38] Men are more commonly affected than women. Although these abnormalities abut the skull base, they are developmental abnormalities of the subarachnoid space rather than of the skull base itself. In the early embryo there are no subarachnoid spaces around the brain. The forming brain is surrounded by loose mesenchyme, and all CSF is contained within the ventricles. It is hypothesized that as pulsations of the CSF force fluid into the subarachnoid space during normal development, some of the CSF becomes trapped between the developing pia and the arachnoid.[39] These cysts can occur in many locations; the middle cranial fossa is a frequent site. The cysts can expand progressively during antenatal development. The exact mechanism of this enlargement is unknown, although many theories have been proposed.[39] At imaging, the wings of the sphenoid can be remodeled. The greater wing is frequently thinned and pushed forward, and the lesser wing may be elevated. The cyst itself has a characteristic appearance on the imaging following the appearance of CSF on either CT or MR imaging. These cysts are dark (no restricted diffusion) on diffusion-weighted imaging, helping to differentiate them from an epidermoid in questionable cases.

Another congenital abnormality that has a secondary effect on the skull base is the Arnold-Chiari malformation. The inferiorly displaced brainstem can appear to cause a pressure effect on the clivus, giving it a scalloped, more vertical appearance. This is an incidental finding because the changes in the brain itself are far more obvious.

VIEW IMAGE

FIGURE 12-25 Neurofibromatosis with congenital defect of the sphenoid. The lesser wing of the sphenoid (*large black arrowhead*) and the superior orbital fissure (*small black arrowhead*) can be identified on the normal side. These two structures are not visualized on the abnormal side because of the maldevelopment of the lesser and greater wings of the sphenoid.

Cartilage Dysplasias

Because most of the sphenoid bone develops from cartilaginous precursors, various cartilage dysplasias will have an effect on the growth of the sphenoid bone. These are discussed later in this chapter.

Inflammation and Obstruction

A variety of inflammatory processes can involve the central skull base. Chief among them is sphenoid sinus infection. Infection can spread to the bone and to the cavernous sinus, causing cavernous sinus thrombosis.

Inflammatory changes in the sphenoid sinus have the same imaging appearance as sinusitis in other sinuses (Fig. 12-31) (see Chapter 5). Mucosal thickening and fluid can be identified, and chronic sinusitis can lead to sclerosis of the bony walls (Fig. 12-32). Fungal infections can invade the wall, reaching the cavernous sinus (Figs. 12-32 and 12-33), and thrombosis of the carotid artery and cavernous sinus can occur. Thrombosis can be identified on imaging as filling defects replacing the normal enhancement of the cavernous sinus (Fig. 12-34).[40] Venous channels leading to and from the cavernous sinus may be thrombosed. The inflammatory tissue does enhance and may blend with the enhancing sinus mucosa on CT. The cavernous sinus may bulge laterally, and the dura may enhance. Eventually, narrowing of the carotid artery can be seen within the sinus.

Necrotizing (malignant) otitis is an invasive pseudomonal infection that occurs almost exclusively in elderly diabetics and starts in the external auditory canal.[41–44] The infection can then spread across the soft tissues beneath the skull base and can even cross the midline. Invasion of the petroclival fissure or the central basicranium can occur in

later stages, and MR imaging can show obliteration of the clival fat.[45–47]

The Tolosa-Hunt syndrome is a presumed idiopathic inflammatory condition involving the orbital apex, superior orbital fissure, and cavernous sinus. This is discussed in Chapter 9.

Obstruction of the sphenoid sinus can result from the sequelae of inflammatory disease or rarely from tumor. Early in the process, the obstructed sinus secretions have a low (10 to 25 HU) CT attenuation. If the secretions become desiccated, their attenuation increases. *Aspergillus* colonization of the obstructed sinus cavity may add to the density as well. Eventually, the sinus may become very dense, mimicking the appearance of enhancement on nonenhanced scans. On MR imaging the signal intensities vary with the protein concentration of the obstructed secretions (Fig. 12-35).[48–50] With extreme desiccation, particularly when combined with *Aspergillus* colonization, the appearance may be ''black'' on all sequences. This topic is discussed in Chapter 5.

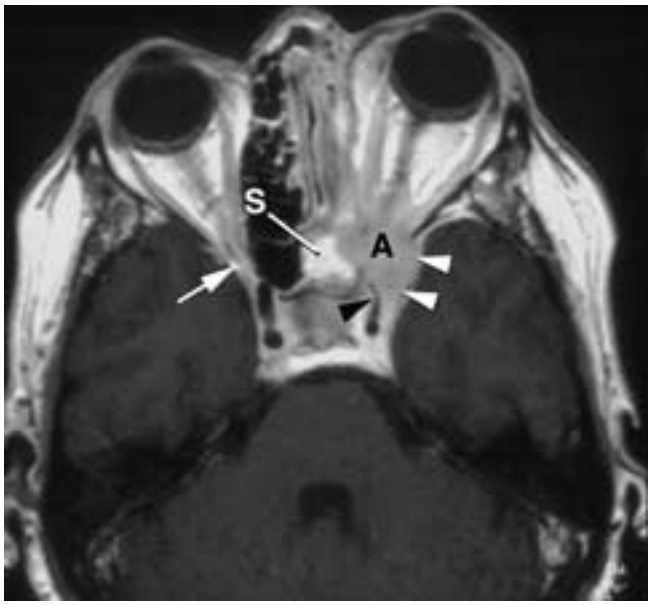

FIGURE 12-33 *Aspergillus* of the sphenoid sinus extending into the orbital apex and cavernous sinus. Axial postcontrast T1-weighted image shows the *Aspergillus* (*A*) with moderate enhancement. The lesion was intermediate to slightly dark on T2-weighted images. There is expansion of the anterior cavernous sinus (*white arrowheads*), with narrowing of the carotid artery (*black arrowhead*). There are retained secretions in the more medial sphenoid sinus (*S*). Note how the bright fat protruding through the superior orbital fissure is obliterated on the left side. Compare this to the normal fat on the right side (*white arrow*).

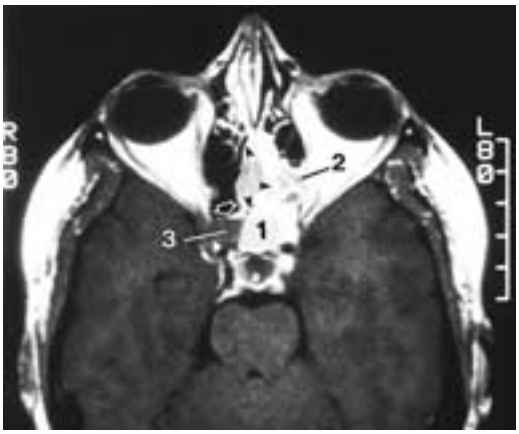

FIGURE 12-35 Esthesioneuroblastoma. The small tumor shows intermediate enhancement and causes the region of the nasal septum to bulge in all directions (*small black arrowheads*). The sinuses show various signal intensities reflecting various protein concentrations. The bright signal in the left sphenoid (*1*) could be due to a fairly high protein concentration or to hemorrhage. The intermediate signal intensity in the posterior left ethmoid (*2*) shows a lower protein concentration than in the left sphenoid. The low signal in the right sphenoid (*3*) is typical of relatively recent obstruction with high water and low protein concentrations. The enhancement of the mucosal margin (*open arrow*) also helps differentiate the obstructed sinus from the tumor.

apparent site of origin of a primary tumor is a helpful indicator of the lesion's histology, and subtle differences in location can cause the radiologist to favor one diagnosis over another.

Tumors develop according to the tissues present in a particular region. Hence, based on the anatomy, the skull base can be organized into three general regions (Fig. 12-36). In the midline, the sphenoid is a block of bone perforated by a sinus and covered by dura. Two important embryologic structures, the notochord and Rathke's pouch, pass through this part of the bone. Any of these tissues can contribute to pathology. Hence, in the midline, there can be chordomas (notochord), meningiomas, bone and sinus tumors, and rare lesions related to Rathke's pouch remnants.

Just off the midline in the sagittal plane of the fissures and formina, one still finds meningeal lesions. The lateral recess of the sphenoid sinus can extend into this area, so that pathology related to the sinus as well as rare bone lesions

VIEW IMAGE

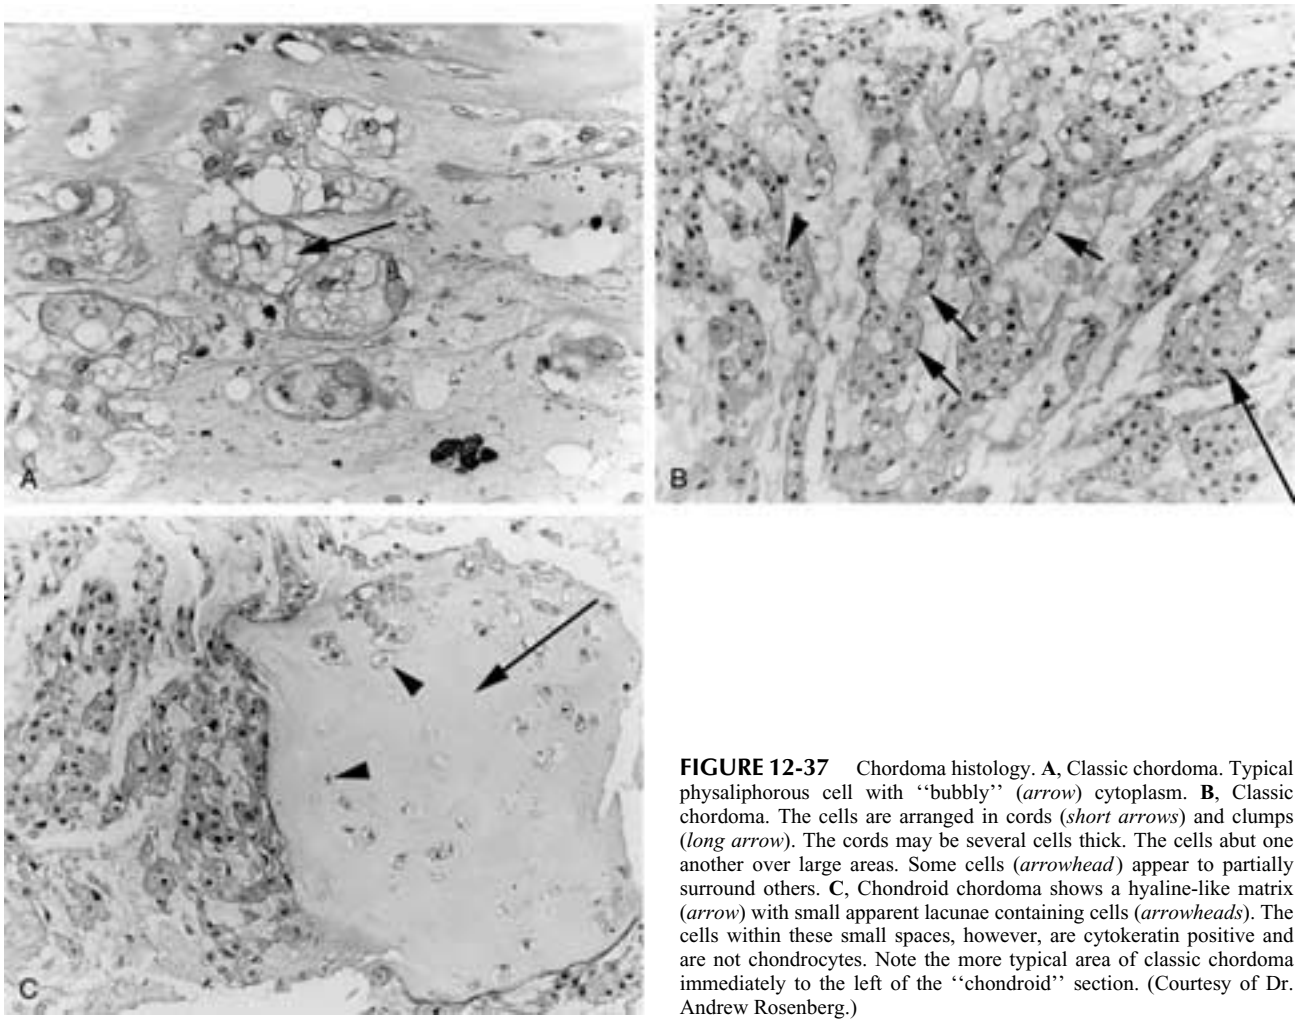
FIGURE 12-36 The sphenoid bone can be divided into three basic regions. In zone 1, the central sphenoid, lesions are predominantly related to bone, dura, sella, or the sphenoid sinus. Lesions arising in zone 2 may arise from dura but also arise from nerves and vessels. The lesions in zone 3 are usually related to the bone or dura. Metastases and meningiomas are common here.

can present here. Chondroid lesions are common here because the foramen lacerum and petrooccipital fissure contain cartilage. The various foramina carry nerves and vessels, so that nerve sheath tumors and aneurysms can arise here. Further laterally in the greater wing of the sphenoid, there are no fissures and foramina. This region is simply a bone covered by dura, and the lesions arising here reflect this simplicity. Most lesions are meningiomas or bone-related tumors. In this region, osseous metastases are also common. Certainly there is overlap in the anatomy and in the resultant pathology that occurs in these areas. However, analysis based on these general regions of the bone can be a helpful beginning to diagnosis.

Chordomas

Chordomas are malignant neoplasms arising from remnants of the embryonic notochord. More than one-third of these tumors arise in the skull base.[55–57] The terminus of the notochord is in the sphenoid bone just inferior to the sella turcica and the dorsum sella, and thus the skull base chordomas arise in the region of the clivus. Thirty-five percent of chordomas occur in the skull base compared with 50% in the sacrococcygeal region and 15% in the spine.[58]

Histologically, the lesion has a characteristic cell, the physaliphorous cell, with large vacuoles containing mucin and glycogen and with a ''bubbly'' appearance of the cytoplasm (Fig. 12-37).[58, 59] The cells tend to clump



VIEW IMAGE

FIGURE 12-37 Chordoma histology. **A**, Classic chordoma. Typical physaliphorous cell with ''bubbly'' (*arrow*) cytoplasm. **B**, Classic chordoma. The cells are arranged in cords (*short arrows*) and clumps (*long arrow*). The cords may be several cells thick. The cells abut one another over large areas. Some cells (*arrowhead*) appear to partially surround others. **C**, Chondroid chordoma shows a hyaline-like matrix (*arrow*) with small apparent lacunae containing cells (*arrowheads*). The cells within these small spaces, however, are cytokeratin positive and are not chondrocytes. Note the more typical area of classic chordoma immediately to the left of the ''chondroid'' section. FIGURE 12-38 Chondrosarcoma histopathology. **A**, Myxoid chondrosarcoma. The cells (*arrow*) are true chondrocytes. They are negative for various epithelial markers including cytokeratin. Note how the cells abut one another end to end but do not form true cords. There are only small areas of contact between ends of cells. The cells are within a myxoid matrix. **B**, Hyaline-type chondrosarcoma. The cells are found within true hyalin matrix. The cells (*arrowheads*) are within small lacunae. These cells do not stain for various epithelial markers and are true chondrocytes. (Courtesy of Dr. Andrew Rosenberg.)

together into nests or chords (Fig. 12-37B), and adjacent cells have large segments of contact, at times partially wrapping around one another. The myxoid matrix surrounding the cells gives the tumor a gray, translucent appearance at gross examination. Small dystrophic calcifications and hemorrhages can also be seen.

A variant of chordoma has been described based on the histologic appearance (Fig. 12-37C), as regions within this variant resemble the hyaline type of chondrosarcoma (Fig. 12-38). This lesion was referred to as a ''chondroid chordoma'' by Heffelfinger et al. in 1973.[58] Small cells resembling chondrocytes are found in a matrix that resembles the hyaline matrix of the hyaline type of chondrosarcoma (see below). This tumor was thought to be a chordoma with cartilaginous differentiation. The variations in the designation received significant attention in the literature because of perceived differences in prognosis between classic chordoma and chondroid chordoma. However, immunohistochemical techniques have indicated that neither the cell nor the matrix of the ''chondroid'' portion of this variant is of true chondroid derivation. The cells in these regions stain positive for cytokeratin and for other epithelial markers such as epithelial membrane antigen and carcinoembryonic antigen. Such epithelial markers, particularly cytokeratin, are almost always negative in a true chondroid lesion but are positive in cells of classic chordoma and in notochordal tissue.[59] The term ''chondroid'' in chondroid chordoma, therefore, refers only to a histologic mimic. The lesion does not contain true cartilage or tissue of cartilage origin and thus is not a dimorphic tumor. Notably, both the original descriptions by Heffelfinger et al. and the cases labeled immunohistochemically as ''chondroid'' chordomas more recently by Rosenberg et al. contained not only regions of ''pseudocartilage,'' but also areas of the typical classic chordoma.[58, 59] The controversy regarding separation of chordoma and chondrosarcoma is further described later in this chapter under ''Chondrosarcoma.''

A final type of chordoma is the dedifferentiated chordoma. This type usually arises in the sacrococcygeal region rather than in the skull base. The dedifferentiated component is usually malignant fibrous histiocytoma or occasionally osteosarcoma. These tend to be very aggressive tumors with a poor prognosis.

Skull base chordomas arise within the basiocciput basisphenoid. Rarely, a chordoma can arise in the nasopharynx or can be completely intracranial in location. These locations are explained by the tortuous course of the notochord. Though most of the pathway of the notochord is within the osseous basicranium, short segments of the course transiently pass out of the bone into the soft tissue of the nasopharynx and into the posterior fossa. The passage of the notochord into the posterior fossa also explains a normal variant found in the dura or subarachnoid space of the midline posterior fossa at the level of the pons. A small amount of notochordal tissue occasionally can be present and is referred to as ecchordosis physaliphora. This tissue is also positive for cytokeratin and other epithelial immunohistochemical markers. Though usually small, this benign tissue occasionally can be fairly large. The descent of the notochord into the nasopharynx is believed to be related to the development of the pharyngeal bursa and therefore Thornwaldt's cyst. This is discussed in Chapter 28.

Chordomas can occur at any age, but in the craniovertebral area most cases are diagnosed between the ages of 30 and 50 years. This contrasts with the sacrococcygeal chordomas, which have a peak incidence in the 40- to 60-year age group. Men are more commonly affected than women. There have been cases reported of apparent familial lineage of chordoma.[60, 61] Cytogenetic analysis has been done in a few cases, with variable results.[60–62]

Common presenting symptoms of craniovertebral chordomas include orbitofrontal headaches and visual disturbances. The headache may result from involvement or stretching of the dura. Visual problems or ophthalmoplegia can result when the optic nerves and neural contents of the cavernous sinus are involved. Tumors can involve the trigeminal nerve and eventually can affect cranial nerves VII and VIII as the lesion approaches the internal auditory canal.

Copyright © 2003, Mosby, Inc. All rights reserved.

More inferiorly, cranial nerves IX through XII can be affected. Tumors can also cause symptoms by growing into the pituitary gland or by pushing the brainstem. Lesions extending into the nasopharynx can cause problems with breathing.

On CT, the chordoma is usually a midline clival lesion with both bone destruction and a soft-tissue mass. The margin between the tumor and normal bone is not sclerotic.[63] Radiodensities are frequently present and tend to be fairly large (Fig. 12-39). These densities are not calcifications and are thought to represent remaining fragments of the destroyed bone rather than new matrix formation.[64] Specifically, these tumors do not tend to show the small, calcified ringlets that may be present in chondrosarcomas. The expanding tumor may cross the petrooccipital fissure to reach the petrous bone or may extend intracranially, pushing the pons and brainstem posteriorly. Those rare tumors that occur outside of the bone, either intracranially or in the soft tissues of the nasopharynx, may or may not erode bone. At least part of the soft-tissue component of the tumor will enhance after intravenous contrast, but frequently there are regions that do not enhance and remain of relatively low density (Fig. 12-39). Cystic areas commonly are seen within the tumor.

The MR imaging appearance is quite variable. Usually there is a hypointense to isointense soft-tissue mass on

FIGURE 12-39 **A**, Chordoma. T1-weighted image without gadolinium administration. The tumor (*T*) is fairly homogeneous in the area of the lower basiocciput. The carotid (*arrowhead*) beneath the skull base is deviated laterally by the tumor. The nasopharynx, including the mucosa, is pushed forward. **B**, Axial T2-weighted image shows the high signal of the chordoma. **C**, CT scan done after intravenous contrast administration shows areas of low density (*arrow*) and fairly large ''calcifications'' representing residual bone from the destruction of the lower clivus.

FIGURE 12-40 Chordoma. T1-weighted image after contrast administration shows the tumor (*T*), with fairly homogeneous intermediate enhancement without cystic areas.

T1-weighted images (Figs. 12-39 and 12-40).[65, 66] Cystic areas, large or small, containing hemorrhage or mucoid material, are frequently present and can be bright on T1-weighted images (Fig. 12-41). Occasionally, a remaining piece of bone is large enough to cause a signal void. On T2-weighted images, the tumors characteristically have a high signal intensity.[67] Old hemorrhage may be seen as dark areas on T2-weighted sequences (Fig. 12-42). MR imaging is excellent for detecting the margin of the lesion close to the cavernous sinus and for determining the relationship of the tumor to the brainstem.

Angiography shows a relatively avascular lesion without large intratumoral blood vessels. The normal vessels in and around the basicranium are frequently displaced by the tumor.

Chordomas grow slowly, and metastasis is quite rare. However, even after radical surgery, local recurrence is frequent.[68] Seeding along the surgical entrance pathway can also occur (Fig. 12-43).[69] ''Drop'' metastasis seeding the subarachnoid space of the spine has been reported but is uncommon.[70] The tumor's location within the clivus and its proximity to both carotid arteries and multiple cranial nerves make complete resection almost impossible in many cases. Treatment is frequently a combination of surgery and radiation therapy.[71] Chordomas are resistant to conventional radiotherapy, but success has been achieved with proton beam therapy, focused radiation therapy, and radiosurgery.[72–75] Often the tumor is partially resected to diminish the volume or to move the tumor away from critical structures prior to proton beam therapy.[76]

After radiation therapy, the lesion is not expected to disappear. Rather, control is considered if there is lack of growth and progression of symptoms. The indicated 5-year control rate after proton beam therapy has been 55% to 70%. A poorer prognosis has been described in women, in patients whose tumors show necrosis on imaging, and in patients who have tumors with measured volumes greater than 70 ml.[77, 78] Of note, a recent study indicated that chondroid chordoma (keratin positive) had the same prognosis as standard chordoma and did not share the better prognosis of

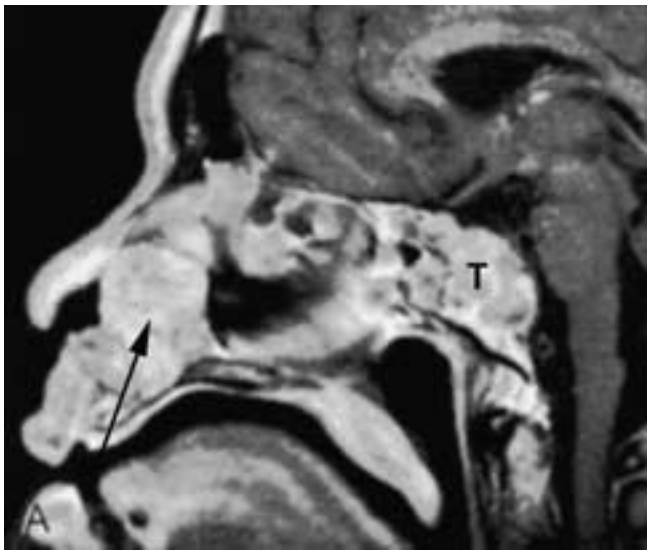
chondrosarcoma (see below).[79] Complications of radiation therapy, including proton beam therapy, include radiation optic neuritis and necrosis. Radiation change is frequently seen in the temporal lobes, where edema, gliosis, or even radiation necrosis can be present (Fig. 12-44).

Chondrosarcomas

Chondrosarcomas can arise from bone, cartilage, or even tissues without a cartilaginous component, and 6.5% of these tumors arise in the head and neck region.[80–82] In the skull base, chondrosarcomas are most commonly found in the region of the various synchondroses that remain after ossification replaces the embryonic chondroid basal plate. These tumors have a particular propensity for the petro-occipital (petroclival) synchondrosis or fissure (Figs. 12-45 to 12-47), and thus chondroid tumors in the deep skull base region tend to be off midline. The junction of the nasal septum and the rostrum of the sphenoid is another location where these tumors tend to arise (Fig. 12-48).[83] Chondrosarcoma can arise in the midline basisphenoid/basiocciput, presumably related to the sphenooccipital synchondrosis.



VIEW IMAGE

FIGURE 12-43 Recurrence of chordoma after the transsphenoidal approach to partial resection. Much of the tumor (*T*) remains in the upper basicranium. Note the recurrence (*arrow*) in the anterior part of the nasal septum.

Chondrosarcoma invades locally but seldom metastasizes.[84] Tumors spread away from the petrooccipital fissure, involve the clivus and petrous portion of the temporal bone, and bulge into the subarachnoid space cisterns or into the soft tissues beneath the skull base.

Chondrosarcomas vary in histologic type. Conventional chondrosarcoma includes the hyaline and myxoid types or a combination of the two (Fig. 12-38). Other types of chondrosarcoma include clear cell, dedifferentiated, and mesenchymal. Virtually all skull base chondrosarcomas are of the conventional type. A recent series of 200 cases showed the combination of hyaline and myxoid types to be most common, occurring in 63% of cases.[79] The relatively pure hyaline type accounted for 7.5% of cases, and the myxoid type accounted for 29.5% of cases. Both histologic patterns include true chondrocytes, but the surrounding matrix differs. The matrix in the hyaline type is more solid compared to the more mucinous or gelatinous matrix seen in the myxoid type. The hyaline matrix can mineralize, giving the characteristic ringlet calcification appearance on CT.

Conventional chondrosarcomas can be graded, reflecting degrees of differentiation. Almost all chondrosarcomas of the central skull base are well or moderately differentiated. Most are slow growing.

Chondrosarcomas can occur at almost any age, but most occur in middle age. The presentation depends on the location and local extension, and headaches or various cranial nerve palsies often cause the patient to seek medical attention.

Treatment may combine surgery with various types of

Copyright © 2003, Mosby, Inc. All rights reserved.

focused beam or particle radiation or may consist of radiation alone.[72, 85] Complete surgical removal is usually impossible due to the location of the lesion and its proximity to neural and vascular structures. These tumors grow slowly, and the prognosis is generally good.

On CT, chondrosarcomas have a varied appearance, depending on the amount of chondroid matrix present.[86] There is usually a significant soft-tissue component that has a dense appearance on noncontrast studies and enhances to some degree after contrast administration. Calcification of the tumor matrix is characteristic but is not always present. Thus, the degree of calcification is quite variable, with some chondrosarcomas having almost no calcification, while others, particularly the low-grade tumors, having extensive, even dense, calcification (Figs. 12-47 and 12-49). The calcifications tend to be small ringlets or incomplete rings, suggesting the cartilaginous nature of the matrix. Frequently, the margin between tumor and normal bone is fairly abrupt, and although this transition zone is fairly narrow, the tumor margin is not sclerotic.

On MR imaging, these tumors usually have an intermediate T1-weighted and a fairly high T2-weighted signal intensity. After gadolinium administration there is detectable enhancement, but the signal change is not profound (Fig. 12-50). Heavy calcifications may be detectable on MR imaging, but smaller ones cannot be seen. Indeed, even if there is fairly extensive calcification, this may not be evident on MR imaging. Therefore, there may be a significant difference between the amount of calcification seen on CT and the size of any MR signal voids that suggest the presence of calcifications.

Chondrosarcoma usually occurs as an isolated tumor, but it can occur as multiple tumors. Chondrosarcoma can occur in Ollier's disease (multiple enchondromatosis) and Maffucci syndrome (multiple enchondromas with associated cutaneous hemangiomas).[87, 88] Chondrosarcoma can also complicate Paget's disease.

Chordoma Versus Chondrosarcoma

Significant controversy surrounds the separation of some chordomas and chondrosarcomas of the central skull base. There is a significant overlap of the histologic patterns of these two tumors, potentially leading to ambiguity in diagnosis. This ambiguity can create problems in planning therapy and determining prognosis.

In the central skull base, there are two histologic types of chordoma and two histologic types of chondrosarcoma. Chordomas are either classic chordoma or chondroid chordoma (Fig. 12-37). Chondrosarcomas are either hyaline or myxoid (Fig. 12-38).[59, 79] The majority of chondrosarcomas are a mixture of myxoid and hyaline histologic types, and virtually all chondroid chordomas also contain regions of classic chordoma histology. There are histologic similarities between the ''chondroid'' part of the chondroid chordoma and hyaline chondrosarcoma and between the classic pattern of chordoma and the myxoid pattern of chondrosarcoma.

As mentioned previously, the term ''chondroid'' in chondroid chordoma refers to a histologic mimic rather than to true chondroid matrix. In the original descriptions of the chondroid chordoma, Heffelfinger et al. referred to a lesion that had areas of classic chordoma as well as regions that histologically resembled hyaline cartilage.[58] The lesion was thought to have cartilage differentiation within a chordoma. The so-called chondroid part of the chondroid chordoma resembles the hyaline-type chondrosarcoma, but the cells are actually typed immunohistochemically as epithelially derived cells rather than chondrocytes. Since the ''chondroid'' component of chordoma resembles hyaline-type chondrosarcoma, one would expect the controversy to be related to this overlapping appearance. However, most of the confusion has actually been between myxoid chondrosarcoma and classic chordoma.

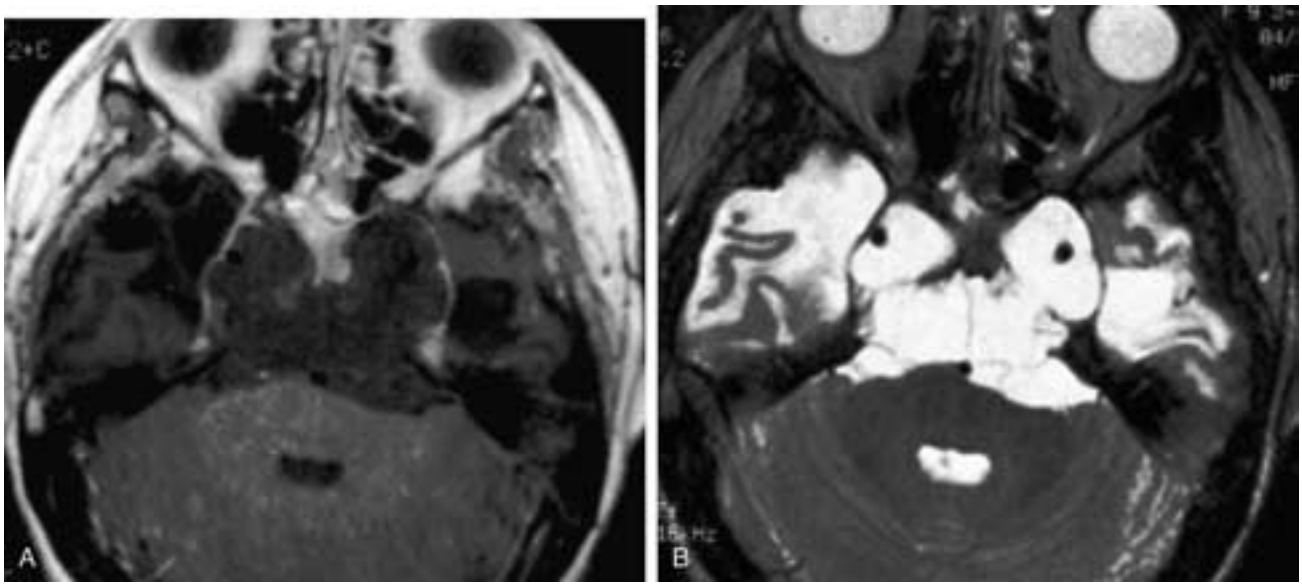


FIGURE 12-44 Chordoma after treatment. **A**, The expansile lesion of the basicranium shows very little enhancement. Note the changes in the contiguous temporal tips from radiation therapy. **B**, Axial T2-weighted image shows the typical high signal within the lesion and abnormal signal in the temporal lobes.

VIEW IMAGE

The myxoid type of chondrosarcoma also has some similarities to the chordoma. The myxoid matrix surrounding cells is similar to that seen in the classic pattern of chordoma. Cells can be found in strands resembling the chord pattern in chordoma. Vacuoles present in some chondrocytes give an appearance resembling the physaliphorous cell of the chordoma. These similarities lead to misdiagnosis of many myxoid chondrosarcomas as chordomas. However, differentiation can be made using the microscopic appearance and immunohistochemical staining.[79]

VIEW IMAGE

FIGURE 12-46 **A**, Chondrosarcoma of the petrooccipital synchondrosis. The tumor (*T*) shows an intermediate signal intensity on this T1-weighted image without contrast. Compare the position of this chondrosarcoma with the normal petrooccipital synchondrosis on the normal side (*arrowhead*). **B**, T2-weighted coronal image shows the tumor (*T*) extending inferiorly through the region of the petrooccipital synchondrosis and the foramen lacerum. The carotid artery (*arrowhead*) is pushed laterally.

In the myxoid chondrosarcoma, the cells tend to abut one another in only a small area at the end of each cell and thus they form chains or strands of cells. In the classic chordoma, cells abut along larger areas, forming larger groups of cells arranged into sheets, nests, and chords, a pattern not found in the chondrosarcoma. Cells may almost completely surround one another. In other words, the ''chord'' is differentiated from the strands found in the CSA by the greater length of cell contact. Chords tend to be more than one cell thick compared to the single-cell strands of cells in the CSA.

The most conclusive evidence, however, comes from immunohistochemical examination.[59, 79] The cells of chon-

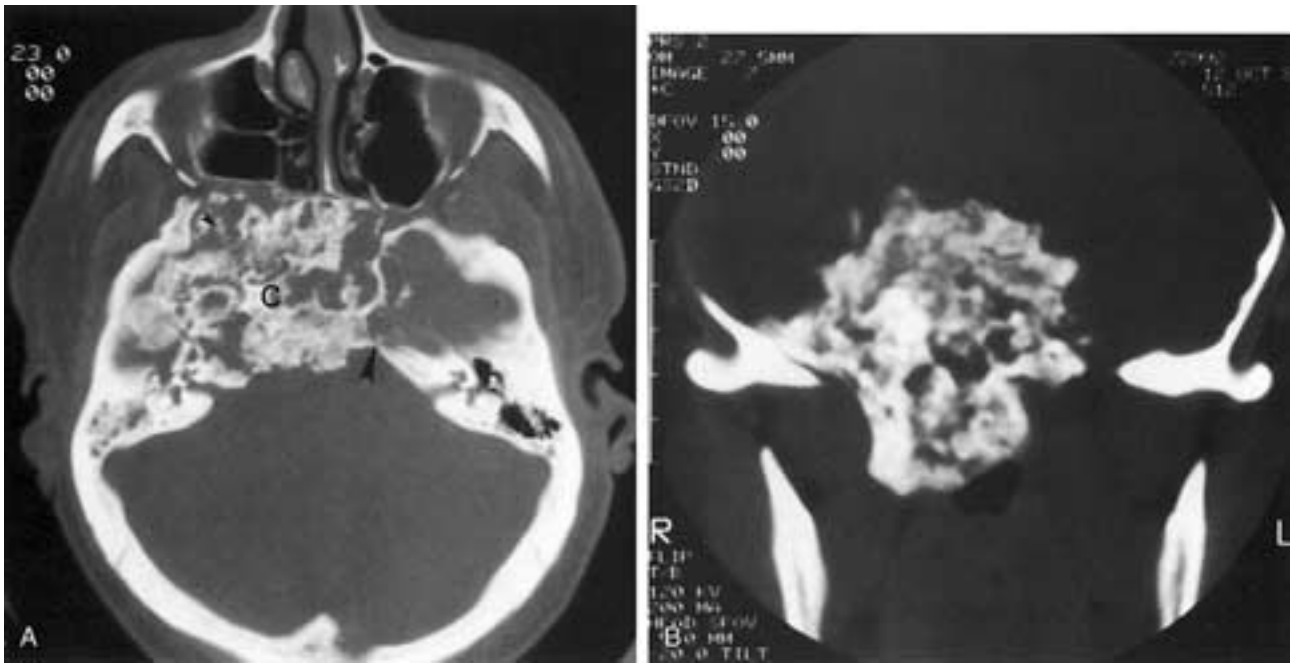
drosarcoma (myxoid or hyaline) are true chondrocytes and do not stain for cytokeratin or other epithelial markers. This is true for chondroid lesions throughout the body. In the chordoma (classic and ''chondroid'') the cells do stain for these epithelial markers, reflecting their origin from the notochord. Notochordal tissue shows the same immunohistochemical profile as the chordoma.

Distinguishing the CSA from the chordoma is important, as the prognosis is quite different. In general, chordomas, including the ''chondroid'' variants, do more poorly than CSA. Although results vary, in a recent report of a large series of tumors treated with a combination of surgery and proton beam therapy, the 5-year control rate was about 51% for chordoma compared to over 90% for CSA.[79]

In the final analysis, one can say that chordoma virtually always arises in the midline and that a lesion arising in the region of the petroclival (petrooccipital) synchondrosis is very unlikely to be a chordoma, but rather is a chondrosarcoma. Chondrosarcomas, however, can arise in the midline related to either the sphenooccipital synchondrosis or the posterior nasal septum. Although the degree and appearance of calcification may give a clue to the identity of a lesion when the site of origin is ambiguous, the location of the tumor's origin is the dominant diagnostic indicator.

Other Chondroid Tumors

Other chondroid tumors of the skull base include chondromas, chondromyxoid fibroma, and, very rarely, chondroblastoma (Fig. 12-51). Truly benign chondromas are



VIEW IMAGE

FIGURE 12-49 Chondrosarcoma of the skull base. **A**, The chondrosarcoma (*C*) replaces much of the body of the sphenoid and the right greater wing. Although the lesion definitely involves and extends across the midline, the center point of the tumor is close to the foramen lacerum. The petrooccipital fissure on the opposite side (*black arrowhead*) is normal. Small ringlets of calcification (*small black arrowhead*) are visualized within the tumor. **B**, Very heavy calcification is seen in this tumor.

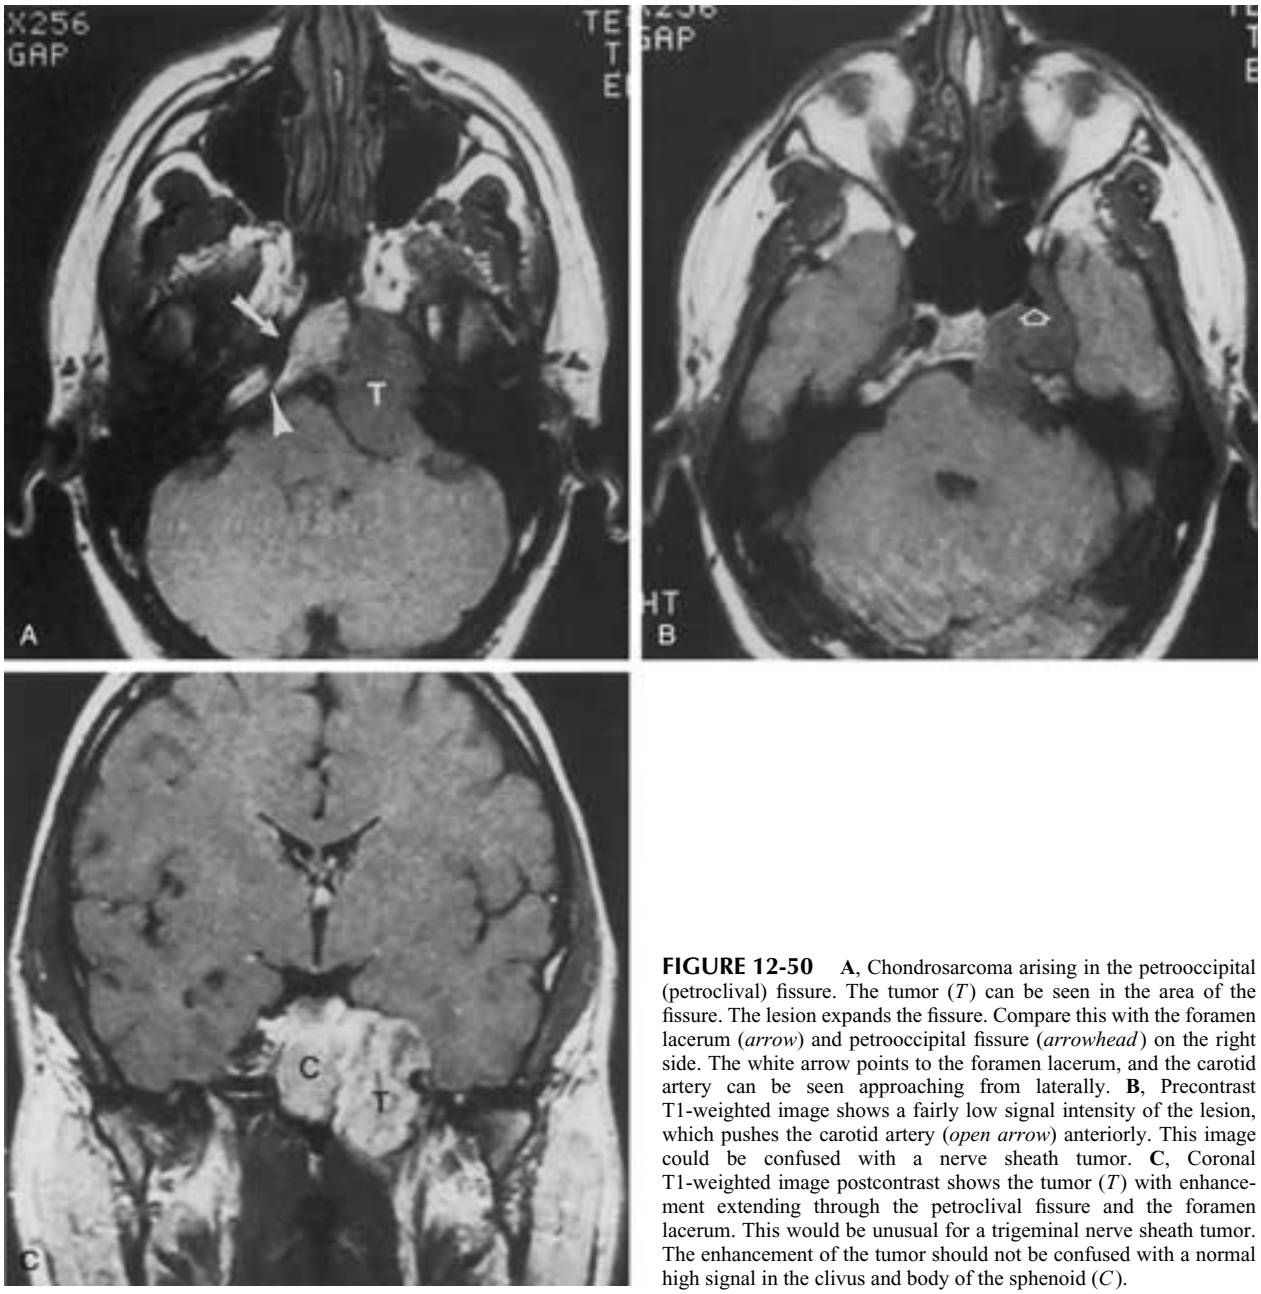

FIGURE 12-50 **A**, Chondrosarcoma arising in the petrooccipital (petroclival) fissure. The tumor (*T*) can be seen in the area of the fissure. The lesion expands the fissure. Compare this with the foramen lacerum (*arrow*) and petrooccipital fissure (*arrowhead*) on the right side. The white arrow points to the foramen lacerum, and the carotid artery can be seen approaching from laterally. **B**, Precontrast T1-weighted image shows a fairly low signal intensity of the lesion, which pushes the carotid artery (*open arrow*) anteriorly. This image could be confused with a nerve sheath tumor. **C**, Coronal T1-weighted image postcontrast shows the tumor (*T*) with enhancement extending through the petroclival fissure and the foramen lacerum. This would be unusual for a trigeminal nerve sheath tumor. The enhancement of the tumor should not be confused with a normal high signal in the clivus and body of the sphenoid (*C*).

VIEW IMAGE

sharply defined and may be calcified. Most are probably more appropriately considered low-grade chondrosarcomas. Rarely, chondromas of the skull base (in addition to the more common chondrosarcomas already mentioned) can be found in patients with Ollier's disease (multiple enchondromatosis) and the Maffucci syndrome (Fig. 12-52) (multiple enchondromas associated with subcutaneous hemangiomas).[87, 88] Several cases were reported in the region of the petrooccipital synchondroses, and astrocytomas can also occur in these conditions.

Chondromyxoid fibroma has been reported as an expansile mass in the skull base.[89, 90] The lesion is not infiltrating and is considered to be less destructive than chordoma, but it may overlap with chondrosarcoma in imaging appearance.

Meningiomas

Meningiomas are benign tumors that arise from the arachnoidal cells of the meninges.[91, 92] The peak incidence is between the ages of 20 and 60 years. Most meningiomas are found either along the convexities or parasagittally. A skull base origin is less common. Meningiomas can arise along almost any part of the sphenoid, including the greater wing, the planum sphenoidale, the tuberculum sella, and the wall of the cavernous sinus. From the initial site of origin, the tumor extends along the dural surfaces or intraosseously, and once it penetrates through the bone, a substantial extracranial mass can develop.

The clinical presentation depends on the site of origin, but headaches can be present with any of these tumors.

Copyright © 2003, Mosby, Inc. All rights reserved.

Meningioma of the planum sphenoidale may cause olfactory symptoms, and tumors closer to the chiasmatic sulcus can cause visual problems. Ophthalmoplegia can result as the nerves in the cavernous sinus are compromised.

The classification of meningiomas of the greater wing of the sphenoid is based on the location of the tumor. If the sphenoid wing is separated into thirds, both the degree of difficulty of resection and the likelihood of cranial neuropathy increase from laterally to medially. Tumors of the medial third, referred to as sphenocavernous meningiomas, are most likely to cause cranial neuropathies and represent the greatest surgical challenge. Recent surgical technical developments have improved surgical access to these difficult tumors, and if such surgery is planned, great precision in the imaging evaluation is required because of the close proximity of the lesion to critical neurovascular structures.

Meningiomas arising from the more lateral portion of the greater wing of the sphenoid may be fairly silent clinically because the cranial nerves are not directly involved. Although some of these meningiomas are globular in shape, many lesions in this location can be classified as hyperostosing en plaque meningiomas. Tumor growth can progress in any direction. As the tumor extends into the orbit, painless proptosis may occur. Inferior growth may cause a mass effect in the infratemporal fossa, presenting as a mass in the cheek or as problems with mastication. Lateral extension growth may displace the temporalis muscle. Medial growth can affect the trigeminal nerve, particularly the third division. Tumors from any location around the sphenoid bone can compress the brain, and seizures may be the presenting symptom.

Because arachnoid cells accompany the cranial nerves, it

VIEW IMAGE

is not surprising that meningiomas can be found adjacent to and traversing various neural foramina.[93] These tumors can cause enlargement or erosion of these foramina, simulating a nerve sheath tumor. Gross destruction of the skull base can simulate malignancy.

On CT, there is enhancement of the soft-tissue component of the tumor. Calcifications may be detectable, and hyperostosis may be seen as thickening of the involved cortex or the trabeculae within the bone. Alternatively, as the meningioma extends through the skull base, a permeative bone pattern rather than a destructive or sclerotic pattern can be seen, often appearing on CT as a ''washed-out'' bone. Meningiomas arising from the planum sphenoidale may show characteristic sclerosis or upward ''blistering'' of the bone (Fig. 12-53). Both plain films and CT can demonstrate this finding.

Pneumosinus dilatans refers to enlargement of an air-filled sinus (Fig. 12-54). Pneumosinus dilatans of the sphenoid can occur either in isolation or in association with meningioma.[94–96] There is some controversy regarding terminology, as there are physicians who use the term ''pneumosinus dilatans'' only when referring to a dilated aerated sinus seen with adjacent tumor. Other people use the term to indicate any expanded air-filled sinus. When occurring with meningioma, the enlargement of the sinus may be focal or diffuse, depending on the position of the tumor, and focal hyperostosis may or may not be present. The enlarged sinus is not opacified unless there is additional inflammatory/obstructive pathology in the sinus itself. The cortex is usually intact, though a focal dehiscence may occur. Pneumosinus dilatans has been described with meningioma arising within the optic canal as well as on the intracranial surface of the sphenoid bone (Fig. 12-55).[97, 98] Apparent enlargement of the sinus can also occur in acromegaly, in fibrous dysplasia, and in Sturge-Weber and Klippel-Trenaunay-Weber syndromes.[99]

On MR imaging, meningiomas are usually isointense to brain parenchyma (Fig. 12-56). After the administration of gadolinium, these lesions enhance intensely (Fig. 12-57). A ''dural tail'' frequently can be seen extending along the dura at the margin of the tumor (Fig. 12-58). Hyperostosis is more difficult to visualize on MR imaging, but sometimes it can be appreciated as an enlargement of the signal void or as a low-signal area representing the cortical bone (Fig. 12-59).

Imaging is particularly important with those tumors in the sphenocavernous region, and the relationship of the tumor to the vital structures of the cavernous sinus is better defined on MR imaging than on CT.[100] Because the normal cavernous sinus often enhances slightly more intensely than the tumor, the interface between tumor and normal structures can be defined. The enlarging tumor often impinges on and may obliterate the CSF signal in Meckel's cave. Tumor also may extend through the bony medial wall of the cavernous sinus

FIGURE 12-53 Meningioma in a 52-year-old female presenting with headache and altered mental status. **A**, Lateral plain film of the skull demonstrating hyperostosis in the region of the planum sphenoidale (*curved arrows*). **B**, Axial contrast-enhanced CT slice through the region of the planum demonstrating a large, expansile mass occupying the floor of the anterior cranial fossa emanating from the planum sphenoidale. Irregular enhancement and bony destruction are apparent.

to appear as an enhancing mass within the sphenoid sinus. Here there can be difficulty distinguishing the tumor from any inflammatory mucosal disease or primary malignancy within the sinus.

One of the most important relationships to note is the effect of the tumor on the internal carotid artery, as meningiomas can surround and frequently will narrow this vessel (Figs. 12-56 and 12-57).[101] A more superior tumor extent can involve the middle cerebral artery. Meningiomas also have been described following the carotid artery inferiorly into the petrous carotid canal.

Craniopharyngiomas and Rathke's Pouch Cysts

The craniopharyngioma arises from remnants of the pharyngohypophyseal (Rathke's) pouch, and most of these benign tumors are found in the sella or in the suprasellar cistern. Those lesions arising in the sellar or suprasellar region can grow into the sphenoid bone. Rarely, a craniopharyngioma occurs completely within the sphenoid bone, presumably developing from remnants of the pharyngohypophyseal duct trapped within the bone (Fig. 12-60).[102–104]

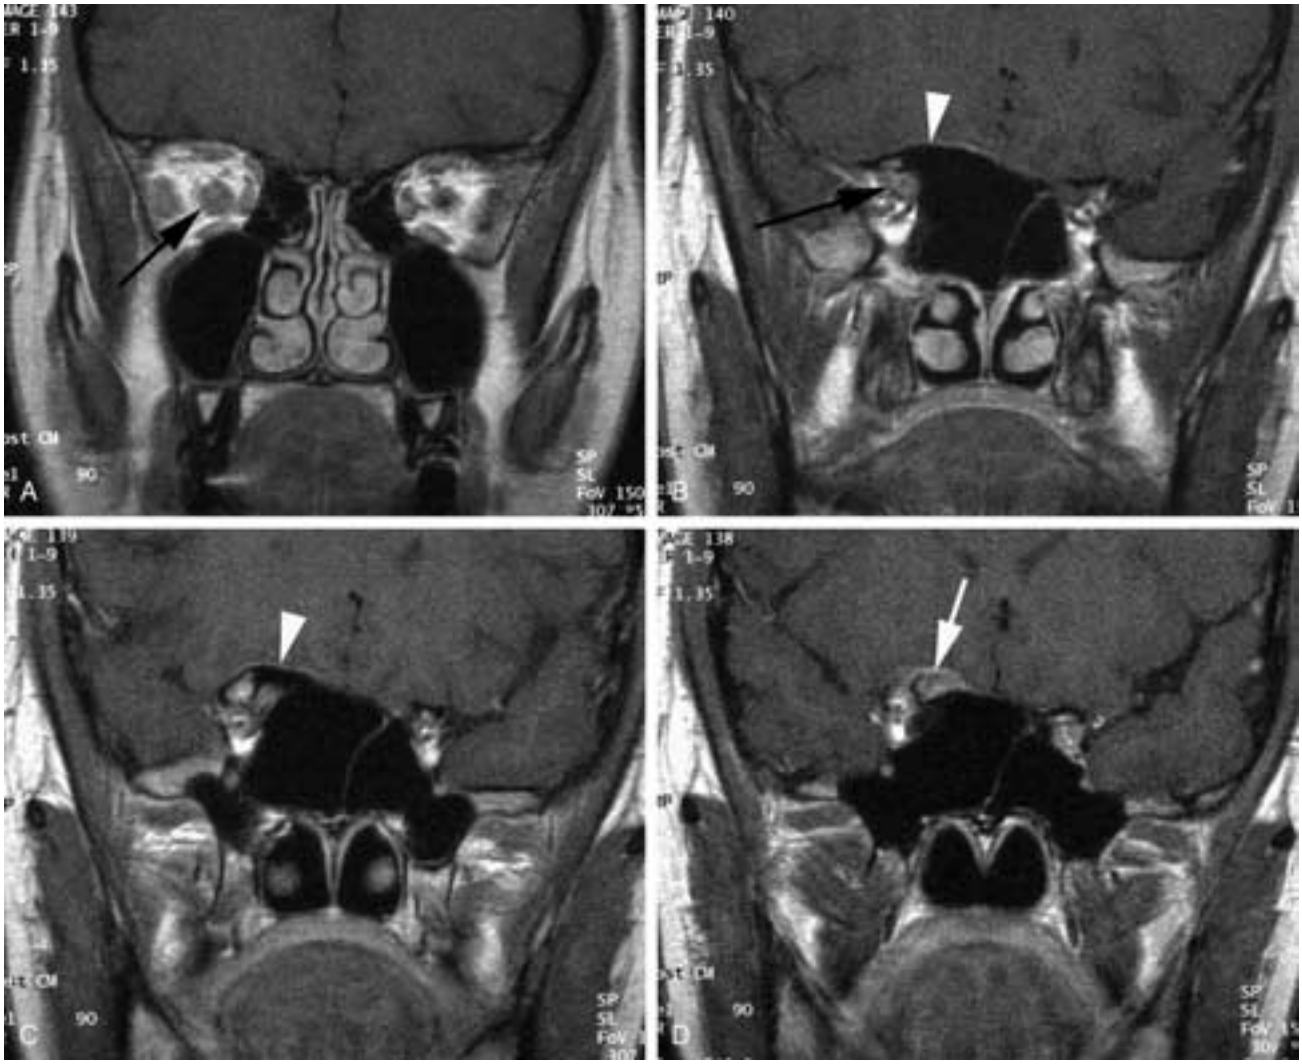
Although craniopharyngiomas are described in Chapter 11, they are included here because of the very rare intraosseous occurrence of the tumor. Though these lesions occur predominantly in the first two decades of life, they can occur at any age; indeed, several of those reported in sphenoid bone have occurred in older patients. Those that are predominantly in the sphenoid bone can extend upward into the pituitary fossa and result in decreased pituitary function. Optic nerve abnormalities are not common with these ''intraosseous'' tumors unless there is further extension into the suprasellar cistern or involvement of the optic canals.

The craniopharyngioma is very similar histologically to some odontogenic lesions, as the pharyngohypophyseal pouch is an ectodermal evagination from the embryonic oral cavity, anterior to the buccopharyngeal membrane, and may develop oral ectoderm-related histopathology.[105, 106] The similarity of the craniopharyngioma to the ameloblastoma has given rise to the term adamantinomatous craniopharyngioma. According to some authors, some of the histologic features of craniopharyngioma more closely approximate the keratinizing and calcifying odontogenic cysts than they do the ameloblastoma.[105]

Histologically, the adamantinomatous craniopharyngioma contains epithelial lobules with palisading nuclei along the periphery. Cystic spaces are filled with fluid or debris, and the so-called wet keratin is considered characteristic of this form of craniopharyngioma.[107] Wet keratin is a conglomeration of large, keratinized cells with ''ghost'' nuclei reflecting the necrobiotic nature of these cells. Calcifications are frequently seen within the lesion, and an inflammatory response along the periphery of the tumor can stimulate bone formation. This is the type of histology that accounts for the typical imaging appearance of the craniopharyngioma with cyst formation and calcification. Reports of infrasellar craniopharyngiomas are rare, but some of the findings that are characteristic of the suprasellar type are found in these infrasellar lesions. The tumor may have a



VIEW IMAGE

soft-tissue component that can extend downward into the nasopharynx or anteriorly into the nasal cavity. Cyst formation and calcification can be found within the tumor or at its margin. Sclerotic changes within the sphenoid bone may reflect the inflammatory component of the lesion.[102]

A rare form of the tumor is the papillary or papillary-squamous craniopharyngioma, considered a distinct variant.[108–110] This tumor type is seen in adults and is frequently located in the region of the floor of the third ventricle. This entity is more cellular, typically lacks calcification, and appears to be more solid at imaging. Cystic components are less common than in the more common adamantinomatous type.

A second type of lesion related to the pharyngohypophyseal pouch is the Rathke's pouch or cleft cyst.[111] Unlike the craniopharyngioma, this cyst is lined by a single layer of epithelial cells, which may be cuboidal or columnar. Goblet cells also can be found frequently. Imaging shows a cystic mass, usually in the sella or suprasellar cistern, with no significant soft-tissue component and smooth, sharp margins. MR imaging can show a low or high T1-weighted signal intensity, depending on the protein content of the cyst fluid. T2-weighted images usually have high signal intensity.

Rathke's cleft cysts also can be found completely within the sphenoid bone (Fig. 12-61). In these cases, differentiation from a mucocele may be impossible. The MR imaging signal intensities are the same, and at biopsy the wall is very similar to that of a mucocele. The cyst contents may be helpful in this regard because the fluid of a Rathke's cleft cyst tends to be yellow and clear, with a low mucoid content.

Such a cyst within the sphenoid bone arises from the remnant of Rathke's pouch. Although the original location of this structure is within the body of the sphenoid, just below the floor of the sella, the variability of formation of the sphenoid sinus may ''push'' the cyst dorsally or superiorly, giving the cyst an eccentric location.

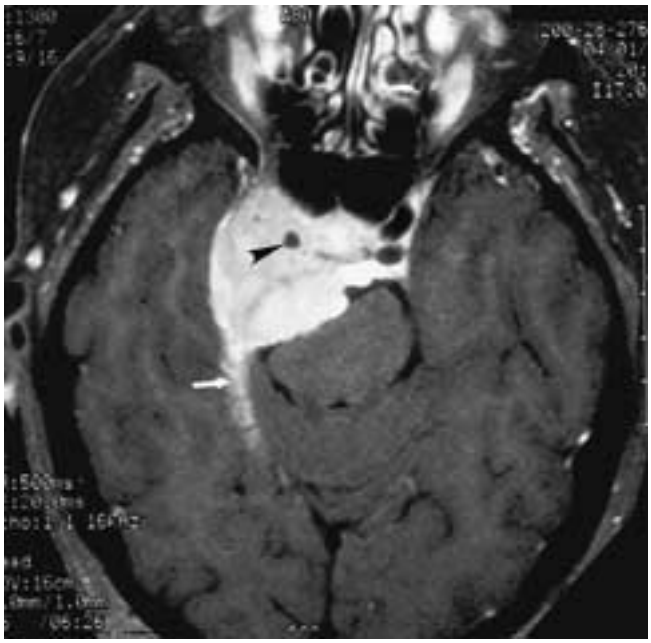

FIGURE 12-57 Meningioma. The tumor fills the region of the cavernous sinus. The carotid artery is narrowed (*black arrowhead*), and there is enhancement extending along the tentorium (*arrow*). Note that although the tumor enhances, one can still separate the margin of the lesion from the enhancement in the venous structures.

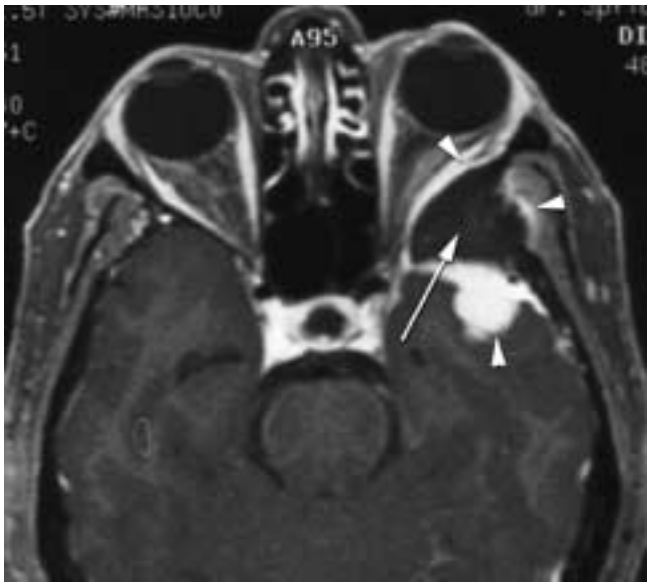

FIGURE 12-59 Meningioma of the sphenoid triangle (greater wing). There is hyperostosis, with an increase in the size of the bone of the sphenoid triangle (*arrow*). There is enhancement in the temporalis fossa, orbit, and middle cranial fossa (*arrowheads*). Note the globular appearance of the intracranial component.

Juvenile Angiofibromas

The juvenile angiofibroma is a benign tumor arising adjacent to the sphenopalatine foramen. Almost all of these tumors occur in adolescent males, and nasal obstruction and epistaxis are the most common presenting symptoms. The tumor is very vascular and thus has a characteristic appearance at imaging (Fig. 12-62). On CT and MR imaging the tumor enhances intensely, and on MR imaging there are flow voids representing the larger high-flow vessels. The location and routes of extension are characteristic and can be seen on either modality. On MR imaging, the tumor tends to have an intermediate signal intensity on T1-weighted

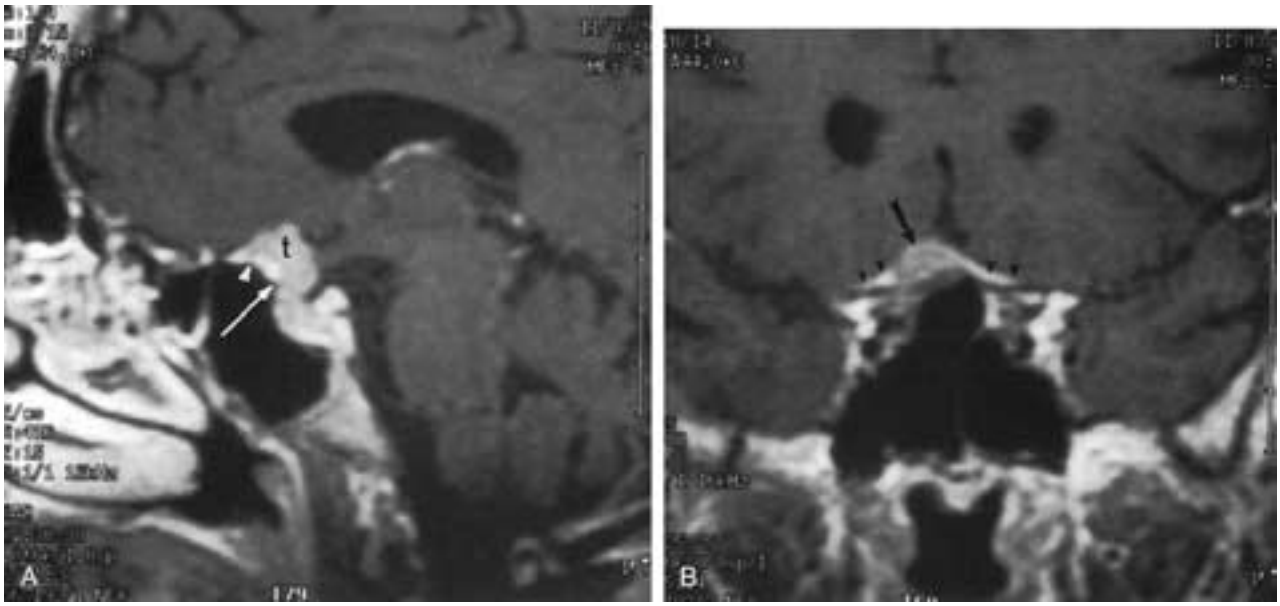

FIGURE 12-58 Meningioma of the chiasmatic groove and planium. **A**, Postgadolinium sagittal T1-weighted image shows the tumor (*t*) extending along the chiasmatic groove and onto the planium sphenoidale. The arrow indicates the position of the tuberculum sella, and the small white arrowhead indicates the limbus separating the chiasmatic groove from the planium. Note how the tumor spills over into the sella turcica. **B**, Coronal T1-weighted postcontrast image shows the tumor (*arrow*) with intermediate enhancement. Notice the enhancement of the dural tails (*small black arrowheads*) extending in either direction from the main tumor.

FIGURE 12-62 **A**, Juvenile angiofibroma expanding the pterygopalatine fossa. The T1-weighted postgadolinium MR image shows enhancing tumor in the region of the pterygopalatine fossa. It expands laterally (*open arrow*) into the infratemporal fossa, and medially the tumor passes through the region of the sphenopalatine foramen (*small black arrowheads*) into the posterior nasal cavity (*n*) and nasopharynx. Compare this with the normal pterygopalatine fossa (*white arrowhead*) on the opposite side. Flow voids representing large vessels (*black arrow*) can be seen within the tumor. **B**, CT scan shows the enlargement of the pterygopalatine fossa (*small black arrowheads*) by the enhancing mass. There is remodeling of the posterior wall of the maxillary sinus anteriorly. The pterygoid plates are pushed slightly posteriorly.

images and a relatively high signal intensity on T2-weighted sequences.

The tumor is locally invasive. In almost every case, tumor extends into the pterygopalatine fossa via the sphenopalatine foramen. The fossa is widened and its normal fat content obliterated. As the tumor grows, the posterior wall of the maxillary sinus is pushed anteriorly and the pterygoid plates are remodeled posteriorly. Actual bone erosion can occur at any margin but is frequently seen at the anterior surface of the upper pterygoid process. From this point the tumor can erode into the sphenoid sinus or posteriorly and superiorly through the more central skull base. As the tumor approaches the cavernous sinus and the middle cranial fossa, the dura remains intact initially. As the tumor continues to grow, the outer dural layer may be elevated so that, even if there is apparent tumor extension into the anterior cavernous sinus at imaging, the tumor still remains epidural in location at surgery. Once near the cavernous sinus, the tumor usually parasitizes intracranial vessels (Fig. 12-63). Eventually, though rare, larger tumors can break through the dural barrier and can even invade the brain.

The tumor can also grow laterally from the pterygopalatine fossa into the infratemporal fossa via the pterygomaxillary fissure. Anterior extension initially pushes the posterior antral wall anteriorly, but eventually the tumor can break through and expand into the sinus. Similarly, tumor in the pterygopalatine fossa can break through the pterygoid process or extend superiorly through the inferior orbital fissure into the orbit. Further extension through the superior orbital fissure is a common route of intracranial extension.

Although the tumor extent is mapped anatomically by CT and MR imaging, angiography is done to delineate the blood supply, often as a prelude to embolization. The primary blood supply is almost always from the terminal branches of the internal maxillary or the ascending pharyngeal arteries. Preoperative embolization effectively reduces intraoperative bleeding. Other arteries frequently may supply the tumor. Of particular concern are those coming from the internal carotid circulation. The arteries of the Vidian canal and the foramen rotundum usually fed from the termination of the sphenomaxillary artery can reverse the flow and carry the blood supply from the internal carotid artery to feed the tumor (Fig. 12-64). A blood supply from branches of the ophthalmic artery also has been demonstrated.

Pituitary Adenomas

Pituitary adenomas are discussed in Chapter 11. However, they are mentioned in this section because of their intimate relationship with the skull base. Two types are particularly pertinent to this discussion—the invasive pituitary adenoma and the infrasellar adenoma.

The invasive pituitary adenoma has its site of origin within the pituitary fossa.[112] As most pituitary adenomas enlarge, they extend superiorly through the diaphragm sella into the suprasellar cistern and toward the optic chiasm. Inferior enlargement displaces the sella floor downward. When a tumor actually breaks through the sella floor or grows laterally into the cavernous sinuses, it is considered an invasive pituitary adenoma (Fig. 12-65). The lesion can be

FIGURE 12-63 Juvenile angiofibroma. **A**, Axial postgadolinium T1-weighted image with fat suppression. This extensive tumor extends across the midline into the opposite infratemporal fossa (*open arrow*). There is extensive tumor (*black arrow*) extending intracranially. Flow voids (*arrowheads*) are seen within the tumor. **B**, Coronal postgadolinium T1-weighted image with fat suppression shows extensive intracranial tumor (*black arrow*) protruding superiorly. The lesion parasitized branches of the middle cerebral artery.

very large and destructive, at times reaching the nasopharynx or nasal cavity. In these cases, the imaging differentiation from a malignancy such as nasopharyngeal carcinoma can be quite difficult.[113] One differentiating point is that when a nasopharyngeal tumor invades the cavernous sinuses, it usually encases and narrows the carotid artery. However, when an invasive adenoma invades the cavernous sinuses, these arteries are surrounded but not narrowed. The lesion appears to squeeze around the vessel.

An extremely rare occurrence is a tumor of pituitary histology that is completely within the body of the sphenoid bone (Fig. 12-66).[114, 115] In these cases, the floor of the sella turcica has been reported to be intact. These extremely unusual tumors presumably arise from remnants of the

FIGURE 12-66 Intrasphenoid pituitary adenoma in a 38-year-old female presenting with amenorrhea, galactorrhea, and hyperprolactinemia. Midsagittal (**A**) and coronal (**B**) T1-weighted images show the presence of a mass involving the body of the sphenoid bone. The mass is relatively isointense to brain and extends inferiorly to the nasal fossa and nasopharynx (**A**, *straight arrows*), posteriorly to involve the clivus (**A**, *curved arrow*). It invades both cavernous sinuses (**B**, *asterisk*). A sphenoid sinus malignancy or chordoma also would be in the differential diagnosis.

pharyngohypophyseal pouch trapped by the closing ossification centers of the developing embryo. Another possibility is that the floor of the sella is not intact. In this case, the lesion invades the floor of the sella turcica and pushes or extrudes into the sphenoid sinus. The pulsation of the CSF transmitted through an incomplete diaphragm sella may help push the lesion down. As the lesion is pushed out of the sella, the appearance of an empty sella may be present.

Neurogenic Tumors

The numerous foramina of the sphenoid bone transmit several major cranial nerves and a variety of smaller nerves. Tumors can arise from these nerves.

Schwannomas (nerve sheath tumors) arise from the nerve sheath. Although the tumor can arise from virtually any nerve, the nerve most commonly affected in the central skull base is the trigeminal nerve. Hypoglossal nerve schwannomas are rare, as are lesions arising from cranial nerves III, IV, and VI in the region of the cavernous sinus. Schwannomas of cranial nerves IX, X, and XI arise at the margin of the basicranium in the medial jugular foramen.

The trigeminal schwannoma can arise in Meckel's cave or in the cistern along the course of the nerve (Fig. 12-67). Extension may occur through the foramen ovale, the foramen rotundum, or the superior orbital fissure (Figs. 12-68 and 12-69). When near the petrous apex, these schwannomas frequently have a dumbbell shape, with the anterior component enlarging the cavernous sinus and impinging on the middle cranial fossa, while the posterior component protrudes into the posterior fossa beneath the tentorium (Fig. 12-70). Other trigeminal schwannomas can remain isolated in either the posterior or the middle cranial fossae (Fig. 12-71). Rarely, a schwannoma can arise below the skull base in the masticator space or the pterygopalatine fossa. These tumors can protrude cranially, enlarging the foramen rotundum or the foramen ovale.

Like schwannomas elsewhere, trigeminal schwannomas can be solid or they can have a variable cystic component.

FIGURE 12-68 Schwannoma extending through the superior orbital fissure. Note the lesion in the orbit (*black arrow*) extending through and obliterating the fat of the superior orbital fissure (*white arrowhead*) as the lesion extends into the anterior cavernous sinus (*black arrowhead*). Compare the obliteration of the fat on the left with the intact superior orbital fissure fat on the right (*white arrow*).

The smooth bony margin of an expanded foramen, if present, is best appreciated on CT. The cortex is usually maintained. These tumors enhance with contrast on either CT or MR imaging. On MR imaging, these tumors tend to have intermediate T1-weighted signal intensity. Cystic components can have low or high T1-weighted signal intensity. On T2-weighted images, these tumors have a fairly high signal intensity that is slightly higher than that of brain but is not as high as that of CSF.

Neurofibromas can affect the cranial nerves in neurofibromatosis type I (von Recklinghausen's disease). These lesions are made up of Schwann cells as well as perineural-like and fibroblastic cells.[116] Axons may be seen incorporated within the tumor. The nerve is enlarged and may follow through and expand the foramina (Figs. 12-72 and 12-73).

The plexiform neurofibroma is associated with neurofibromatosis type I. This abnormality is a more diffuse neurofibroma and is more infiltrative than either the localized neurofibroma or a classic schwannoma (Fig. 12-74). The tumor can follow and diffusely enlarge a branching nerve or plexus or can be a major component of a massive soft-tissue neurofibroma, a form of neurofibroma infiltrating diffusely through the soft tissues. Calcifications can sometimes be seen within these tumors on CT scans. The distribution of the trigeminal nerve can be affected, and when the tumor involves the orbit it often can be seen, with its irregular margins, extending into the orbital fat and around the orbital muscles. The plexiform neurofibroma may be associated with enlargement of the superior orbital fissure and with underdevelopment of the greater wing of the sphenoid, findings characteristic of neurofibromatosis I (Figs. 12-24 and 12-75). However, either the bony defect or the plexiform tumor can occur as an isolated lesion. Plexiform neurofibroma can also undergo malignant change. Primary malignant nerve sheath tumors are rare.

Giant Cell Lesions

Giant cell tumors (GCTs) are rare in the sphenoid bone. They have been reported in the body and in the greater sphenoid wing (Fig. 12-76). As in other areas of the body, the GCT of the sphenoid tends to occur in young adults. Most occur in the third or fourth decade of life but can occur at almost any age.[117, 118] A recent report described a series of pediatric patients with the lesion.[118] There is a slight female predominance.

The lesion expands the cortex of the bone but frequently leaves small gaps, producing an interrupted bony shell along the outer margin. There can be marginal sclerosis. With MR imaging, the lesion is described as having relatively low signal intensity on both T1-weighted and T2-weighted sequences. These lesions enhance moderately. Although cysts and fluid-fluid levels with areas of high signal intensity have been described, many GCTs are relatively homogeneous solid tumors.

The tumors may present with headache or cranial nerve palsies. Biopsy shows oval or plump spindle-shaped mononuclear cells and multinucleated giant cells evenly distributed throughout the lesion.[53] Each giant cell can have as many as 50 to 100 nuclei; most have 20 to 30. Reactive bone formation, hemorrhage, and cyst formation have also been described.

The GCT is one of the lesions considered to be a potential precursor of the aneurysmal bone cysts. Cysts can occur in part of the lesion or may replace the entire tumor. GCT can be primary or secondary. Secondary lesions can develop in pagetoid bone.

The giant cell granuloma (giant cell reparative granuloma, central giant cell granuloma) is most common in the mandible and maxilla but has been reported in the skull base, including the temporal bone and sphenoid.[119–123] The word ''central'' in the name central giant cell granuloma refers to a lesion whose origin is in bone rather than within the soft tissues of the oral cavity. Thus, a lesion arising in the gingiva is referred to as a peripheral giant cell granuloma. The giant cell granuloma is considered to be reactive rather than a true neoplasm. Trauma or hemorrhage have been suggested as inciting stimuli, but these are not definable in every case. There is a slight female predominance and the lesions occur at slightly younger ages than GCTs, typically between the ages of 10 and 25 years.[53]

The lesions are lytic and expansile and can have a sharp margin. The cortex is expanded, and the lesion is surrounded by a thin rim of bone. The cortex is frequently interrupted in some segments, and new bone formation has been reported.[123] On MR imaging, the giant cell granuloma tends to have low signal intensity on T1-weighted and T2-weighted sequences and the lesion enhances. There also can be significant hemorrhage into the lesion with cyst formation.

Histology shows giant cells, but they are not as evenly distributed throughout the lesion as in the GCT.[53] Each giant cell has fewer nuclei than the true GCT. In addition to the giant cells there are spindle-shaped fibroblasts, chronic inflammatory cells, and hemosiderin-laden macrophages, as well as collagen formation.

Brown tumors are indistinguishable histologically or radiologically from giant cell granuloma. They tend to occur later, in the fourth and fifth decades of life, and are seen in

Copyright © 2003, Mosby, Inc. All rights reserved.

patients with hyperparathyroidism.[120] They are more common in primary than secondary hyperparathyroidism, though they have been found in patients undergoing long-term dialysis. The serum calcium level is high, and the phosphorus level is low.

Aneurysmal Bone Cysts

Aneurysmal bone cysts (ABCs) occasionally are found in the sphenoid bone. On imaging, they appear as expansile masses with multiple cystic spaces. They have hemorrhage with large, blood-filled cavities, and fluid-fluid levels are characteristic. The patients are almost always less than 20 years old.

Several types of bone lesions have been considered to be precursors to ABCs. GCT, chondroblastoma, osteoblastoma, benign fibroosseous lesions, giant cell granuloma, chondromyxoid fibroma, bone cysts, eosinophilic granuloma, and hemangioma have all been mentioned.[53] Occasionally, an ABC can form within a malignancy. The ABC can have solid regions that mimic giant cell granuloma, with giant cells, fibroblasts, and hemorrhage.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a proliferation of histiocytic and histiocytic like cells.[53] The typical histiocyte like cell is the Langerhans cell. The common histio-

FIGURE 12-70 Nerve sheath tumor of the trigeminal nerve (schwannoma). The tumor (*T*) has both a middle cranial fossa and a posterior fossa component. Note that the carotid artery is pushed medially. **A**, The T2-weighted image shows relatively high signal but areas of intermediate signal as well. **B**, Sagittal image shows the dumbbell configuration of the tumor, with components both above and below the tentorium. The constriction is at the position of the tentorium. **C**, Coronal image shows the tumor expanding the region of the cavernous sinus and obscuring Meckel's cave. A small amount of fat (*arrowhead*) is seen just beneath the foramen ovale, indicating that the tumor did not spread by this route. **D**, Coronal bone algorithm. The foramen ovale between the small black arrowheads is enlarged even though the tumor did not extend through this foramen. Compare with the foramen ovale opposite (*large black arrowhead*).

cyte is a mononuclear cell with phagocytic ability, which contains many intracellular inclusions and lysosomes. The Langerhans cell has fewer lysosomes and less phagocytic ability than the usual histiocyte. The characteristic feature of the Langerhans cell is a folded large nucleus having a kidney or coffee bean shape. The lesion in LCH contains varying numbers of Langerhans cells mixed with eosinophils and more typical histiocytes.

The group of diseases included under the name Langerhans cell histiocytosis includes eosinophilic granuloma, Hand-Schuller-Christian (HSC), disease and Letterer-Siwe disease. These diseases, though related by histopathology, behave very differently. Eosinophilic granuloma (EG) usually has only one lesion at presentation and in such cases behaves clinically like a benign disease. If multiple lesions are present, a less benign course may be present. HSC disease is a chronic disease that is predominantly isolated to one organ complex such as the osseous system. It has a prognosis between those of EG and Letterer-Siwe disease. Letterer-Siwe disease is a multisystem, more acute disease that can be rapidly fatal. The classification is not exact, and there is often overlap. In general, the younger the patient, the

Copyright © 2003, Mosby, Inc. All rights reserved.

more severe the disease. Letterer-Siwe disease almost always presents in the first 3 years of life. HSC usually presents between 3 and 5 years of age and infrequently in slightly older persons. EG usually presents between the ages of 5 and 20 years.

The disease can involve almost any bone. LCH frequently involves the cranial vault and, less commonly, the skull base. The localized lesion of EG is the most likely variant to present as an isolated diagnostic problem in the skull base. Lesions can have a characteristic ''punched-out,'' sharply defined margin or can be more irregular, with a sclerotic margin. In the cranial vault, the lesion classically has a sharp margin with a beveled edge. A ''button sequestrum'' lesion is a lytic lesion in which residual bone remains. In the skull, most lesions are lytic, with or without sclerosis.

At radiography or CT scanning, the lesion may present as a ''punched-out'' abnormality, with a sharp margin and no sclerosis (Fig. 12-77). Alternatively, the lesion may have a more irregular sclerotic margin.[124, 125] On MR imaging, the lesion is seen as a solid mass, often obliterating the signal void of the cortex. The lesion usually has a high T2-weighted signal intensity but occasionally can have a fairly low signal intensity.[126] There is moderate enhancement. High signal intensity can be seen in contiguous soft tissues on T2-weighted images, reflecting the inflammatory nature of the lesion.[125]

Lesions involving the skull base can give cranial nerve palsies or present with pain and inflammatory symptoms. In the temporal bone, the lesion can mimic otitis media; however, there is no improvement on antibiotics. Systemic symptoms and peripheral eosinophilia are occasionally present. Lesions may be treated by curettage or by radiation therapy, depending on accessibility and proximity to crucial structures.

Miscellaneous Tumors and Lesions of the Sphenoid Bone

Though rare, osteosarcomas, Ewing's sarcoma, hemangiomas, and other miscellaneous tumors occasionally can be identified in the skull base. Similarly, lymphoma is uncommon, usually extending into the bone from contiguous soft-tissue disease. The rarity of these lesions precludes definitive statements about their imaging characteristics. However, anecdotal experience has shown that osteosarcoma can occur in the body or wing of the sphenoid.[127, 128] Imaging diagnosis relies on the identification of an osteoid matrix, seen best on CT. Lymphoma is very cellular and has a relatively low T2-weighted signal intensity. The primary mass is usually in the nasopharynx, but lymphoma can occasionally arise within the bone.

Plasmacytoma can affect the skull base and usually has a lytic, fairly homogeneous appearance on CT. On MR imaging, presumably because of cellularity, the tumor usually has an intermediate signal intensity on both T1-weighted and T2-weighted images. The lesion enhances

Lesions are also seen lower in the neck. **D**, Coronal image through the region of the foramen rotundum shows the enlargement of the actual nerve (*arrow*) within the foramen surrounded by the small venous plexus.

on either CT or MR imaging. Although plasmacytoma can occur as an isolated lesion, many of these patients eventually develop multiple myeloma.

Carcinoma occasionally arises from the mucosal elements contained within the sphenoid sinus (Fig. 12-78). The tumor has an appearance similar to that of any invasive malignancy, and the diagnosis may be suggested by the relationship of the tumor to the sinus and surrounding structures.

Vascular lesions are rare in the skull base, and they may be benign or malignant.[129, 130] Benign lesions include hemangiomas or various vascular malformations. Hemangiomas have high T2-weighted signal intensity, may expand the bone, and enhance significantly. The bone may soften, and basilar invagination can result. Vascular malignancies potentially involving the skull base include angiosarcoma, hemangioendothelioma, hemangiopericytoma, and Kaposi's sarcoma.[53, 129]

Copyright © 2003, Mosby, Inc. All rights reserved.

Gorham's disease (massive osteolysis, disappearing bone disease, vanishing bone disease, phantom bone disease) is believed to develop from a vascular lesion.[4, 53, 131–137] Both hemangioma and lymphangioma have been mentioned as underlying lesions. This lesion at biopsy has a mixture of small-caliber blood vessels and fibrosis, with only a few osteoblasts. Both the skull and the skull base can be involved. At imaging, the bone is replaced by soft tissue, and there is a loss of bone volume (Fig. 12-79). The bone ''disappears'' or collapses. Malignancy, infection, and metabolic causes of bone loss must be excluded before the diagnosis is considered. The lesion may stop progressing spontaneously. Both surgery and radiotherapy have been attempted as curative therapies. The final diagnosis of many

FIGURE 12-74 Diffuse neurofibroma extending along branches of the trigeminal nerve. **A**, Axial T1-weighted postcontrast image with fat suppression shows the tumor (*white arrowheads*) extending from the cavernous sinus anteriorly into the orbital apex and upper pterygopalatine fossa. **B**, T2-weighted image again shows the tumor (*arrowheads*), which has a fairly low signal intensity. **C**, Scan inferior to **A** shows the tumor (*white arrowhead*) filling and expanding the pterygopalatine fossa. Compare this with the normal pterygopalatine fossa (*arrow*) on the opposite side. In this fat-suppressed image, the signal within the normal pterygopalatine fossa is low. A laterally extending air cell from the sphenoid sinus (*S*) is seen extending into the attachment of the pterygoid plate. **D**, The tumor is seen in the anterior cavernous sinus and posterior superior orbital fissure (*open arrow*). The arrowhead indicates the approximate position of the foramen rotundum. The normal foramen rotundum on the opposite side (*arrow*) is identified. Again, note that the expanding sphenoid air cell on the normal side extends between the foramen rotundum and the Vidian canal. (Courtesy of Dr. Norman Leeds.)

of these rare tumors is made at biopsy, and usually the role of imaging is to accurately map the lesion.

Mucoceles

Obstruction of the sphenoid sinus ostium can result in a mucocele. The term mucocele is used by radiologists to indicate an airless, ‘‘mucus-filled’’ sinus, with an enlarged sinus cavity. Mucoceles can occur as isolated lesions or in association with polyps or other inflammatory disease. Any part of the sinus can be expanded. The anterior clinoid process is frequently pneumatized and thus can be enlarged by a mucocele (Fig. 12-80). If a mucocele forms near the root of the pterygoid process, where the air cells pass between the foramen rotundum and the Vidian canal, this bone can be enlarged. However, the separation of the Vidian and rotundum canals varies with the degree of air cell development and extension of air cells into the pterygoid process.[19] Thus, asymmetric separation of the foramina alone does not indicate mucocele. As the mucocele enlarges, it can erode or thin the bony cortex of the sphenoid sinus wall or the cortex of one of these foramina. When present, this erosion or scalloping is a reliable indicator of actual sinus expansion. As discussed in Chapter 5, the signal intensities on MR imaging can vary in relation to the protein

Note the demineralization around the optic nerve canal. **C**, Coronal bone algorithm shows a sharp nonsclerotic margin (*arrows*). **D**, T1-weighted MR image shows intermediate signal intensity of the lesion (*arrows*). **E**, Postgadolinium image shows moderate enhancement (*arrow*). **F**, Axial T2-weighted image shows the lesion to be relatively dark. **G**, Coronal postcontrast image shows the lesion bulging the dura superiorly and involving the apex as well as the lateral sphenoid. **H**, Coronal STIR (Short Tau Inversion Recovery) lesion (*arrows*).

concentration of the retained secretions (Fig. 12-81) and the presence of *Aspergillus* or other mycetomas. On contrast-enhanced MR images, a thin line of enhancing mucosa along the wall of the sinus identifies the obstructed nature of the sinus.[138]

Aneurysms

Aneurysms involving the central skull base can arise from the intracavernous portion of the carotid artery or extend from the petrous portion of the carotid, and though most aneurysms occur spontaneously, some occur after trauma (Figs. 12-82 to 12-86).[139] Despite the fact that transsphenoidal approaches to the pituitary gland, endoscopic explorations of the sphenoid, and various skull base approaches to the cavernous sinus put the artery at risk, postsurgical aneurysms (or pseudoaneurysms) are rare. Sphenoid sinus inflammatory disease, especially fungal disease, can extend into the cavernous sinus and cause an aneurysm.

Aneurysms can present with headache. Pressure on the nerves in the cavernous sinus can lead to ophthalmoplegia (with or without headache) or to facial pain. Hemorrhage is unusual. A small aneurysm confined to the cavernous sinus is unlikely to bleed, but larger ones occasionally can rupture.

Depending on its direction of expansion, this type of aneurysm can rupture into the sphenoid sinus or into the subarachnoid space. The rupture can also be into the cavernous sinus, resulting in a carotid cavernous sinus fistula rather than a frank hemorrhage. If the aneurysm contains thrombosis, embolization to more distal arteries can lead to a central neurologic presentation.

An aneurysm of the cavernous portion of the internal carotid artery will enlarge the cavernous sinus; however, a small aneurysm may be undetectable. Usually, an aneurysm bows the lateral cavernous sinus wall laterally. The bony lateral sphenoid sinus wall may be bowed medially into the sinus. Small aneurysms are quite difficult to detect on planar imaging because of the normal tortuosity of the carotid artery. Careful examination of imaging done in multiple planes will lessen the likelihood of overlooking such an

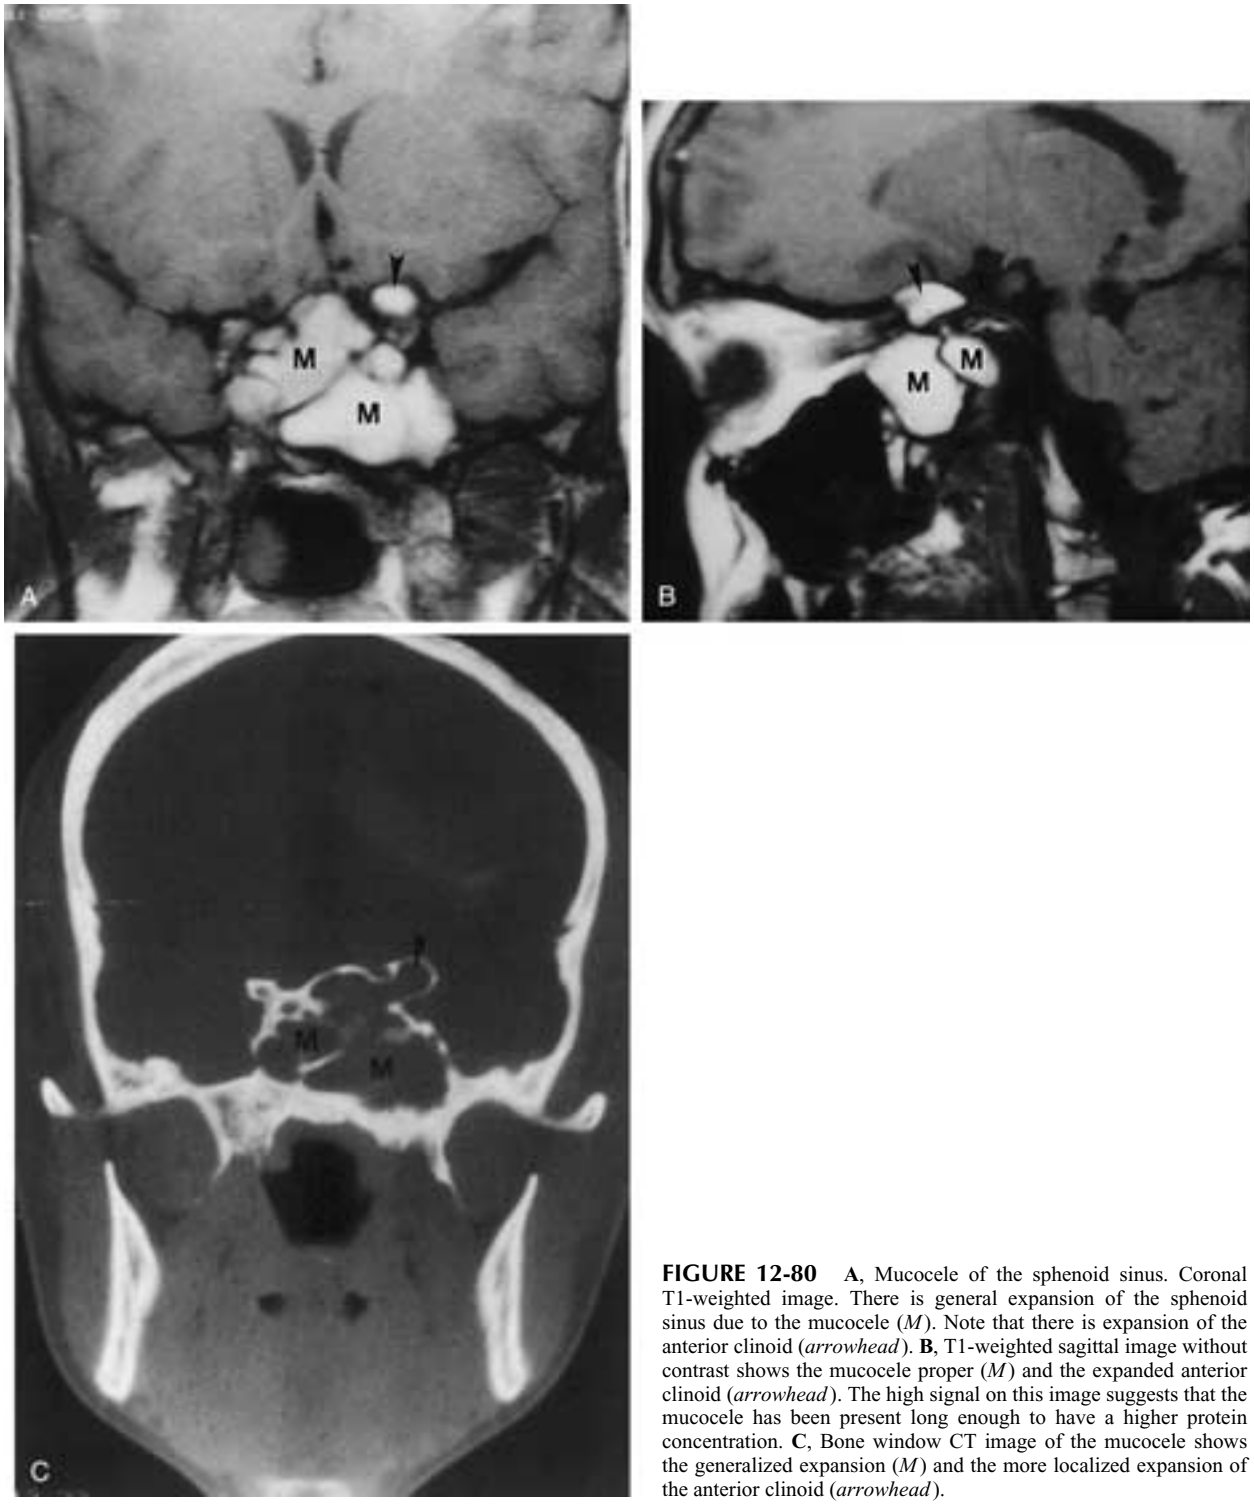

FIGURE 12-80 **A**, Mucocele of the sphenoid sinus. Coronal T1-weighted image. There is general expansion of the sphenoid sinus due to the mucocele (*M*). Note that there is expansion of the anterior clinoid (*arrowhead*). **B**, T1-weighted sagittal image without contrast shows the mucocele proper (*M*) and the expanded anterior clinoid (*arrowhead*). The high signal on this image suggests that the mucocele has been present long enough to have a higher protein concentration. **C**, Bone window CT image of the mucocele shows the generalized expansion (*M*) and the more localized expansion of the anterior clinoid (*arrowhead*).

FIGURE 12-83 **A**, Coronal T1-weighted MR image. Partially thrombosed aneurysm of the petrous and cavernous carotid arteries. The flow void (*arrow*) is seen in the central part of the aneurysm. Most of the ''mass'' is filled with thrombus of varying signal intensities. **B**, Sagittal T1-weighted image without contrast again shows the flow void of the central lumen (*arrows*) within the larger mass, which is partially thrombosed.

aneurysm. If the lumen is patent, MRA or CT angiography may demonstrate the aneurysm. Catheter arteriography is not usually necessary for evaluation of a potential intracavernous aneurysm.

The imaging appearance of a large aneurysm is varied and depends on the patency of the lumen and the presence of partial thrombosis. If little thrombus is present, the lumen may completely opacify on enhanced CT, blending with and ''disappearing'' into the enhancing cavernous sinus. A dynamic CT scan's arterial phase may help separate the aneurysm from the normal cavernous sinus. If, on the other hand, thrombus fills part of the aneurysm, the lesion usually has a low density with an enhancing rim. A channel of opacification, representing residual lumen, occasionally can be seen. Calcification sometimes can be present in the aneurysm's wall.

On MR imaging, the appearance of an aneurysm also varies, depending on the presence or absence of partial thrombosis (Fig. 12-83). The lumen of a small aneurysm still may be detected if there is rapid blood flow causing a signal flow void. Larger aneurysms may be free of thrombus and appear as a large, rounded flow void. However, the flow in the aneurysm may be turbulent, giving a variety of signal intensities. The movement of the blood usually can be defined with various flow-sensitive sequences.

Thrombus, which partially or completely fills the lumen of an aneurysm, has a variable appearance on MR imaging. Layers of thrombus of varying age may be identified, and the appearance reflects the evolution of the blood products within the thrombus.[140] Thrombus of intermediate age is often bright on T1-weighted and T2-weighted images, reflecting concentrations of methemoglobin. This signal is seen most commonly bordering the residual lumen. Low signal areas, usually seen at the periphery of the aneurysm, reflect the presence of hemosiderin.

On rare occasions, these aneurysms, when large, can erode through the skull base, usually in the floor of the middle cranial fossa.[141]

Treatment of the aneurysm depends on its size, its location, and the presenting symptoms. Small aneurysms may be followed, but larger ones are usually treated. Alternatives to surgery include endovascular occlusion of the parent vessel or placement of balloons or coils within the aneurysm.

SECONDARY TUMOR INVOLVEMENT OF THE SKULL BASE

The skull base is frequently the site of tumor spread, involved most commonly by direct invasion from an adjacent primary neoplasm. Hematogenous metastasis from distant primary tumors also occurs. An important route of extension of primary head and neck tumors is perineural spread along the cranial nerves to and through the various skull base foramina.

Direct Encroachment

Tumors that arise close to the skull base frequently invade the bone because the fascial planes of the infratemporal fossa and nasopharynx preferentially direct the spread of neoplasm toward the skull base.[142] Nasopharyngeal cancer characteristically invades the midline skull base.[143] The strong pharyngobasilar fascia wrapping around the posterior

and lateral walls of the nasopharynx can limit lateral tumor growth, directing tumor growth superiorly toward the roof of the nasopharynx. Here the skull base, the undersurface of the sphenoid bone, is unprotected by any fascial layer, and thus the sphenoid bone is frequently eroded by nasopharyngeal carcinoma. Because many of these malignancies arise off midline in the region of the fossa of Rosenmuller, the foramen lacerum and the petrooccipital fissure immediately above this part of the nasopharynx are frequently invaded. Tumor spreading through this cleft, along the lateral aspect of the sphenoid body and basiocciput, can reach the cavernous sinus, middle cranial fossa, or posterior fossa. Such tumors encounter the carotid artery as soon as the foramen lacerum is breached. Erosion may extend through the cortex of the sphenoid bone proper to reach the clival marrow. Although erosion of the cortex is appreciated more easily on CT, high-resolution MR imaging better shows the presence and degree of marrow invasion (Fig. 12-87). Lateral tumor extension may pass over the pharyngobasilar fascia to reach the soft tissues in the upper masticator space, immediately below the foramen ovale. Tumor can then pass upward to reach the middle cranial fossa. Lateral extension also can occur along the eustachian tube toward the middle ear. Tumor can spread to the pterygoid process or through the sphenopalatine foramen into the pterygopalatine fossa. Here there is access to the Vidian canal and foramen rotundum. Usually the Vidian canal and the foramen rotundum are involved by direct tumor extension as tumor

invades directly through the bone at the junction of the pterygoid process and body of sphenoid rather than by true perineural spread, where tumor follows the nerve selectively as a conduit.

Sarcomas, lymphomas, and other malignancies also invade directly into the skull base (Fig. 12-88).[144] Tumors can arise in the infratemporal fossa and erode into the greater wing of the sphenoid bone. The foramen ovale may represent the line of least resistance as a tumor expands within the masticator space.

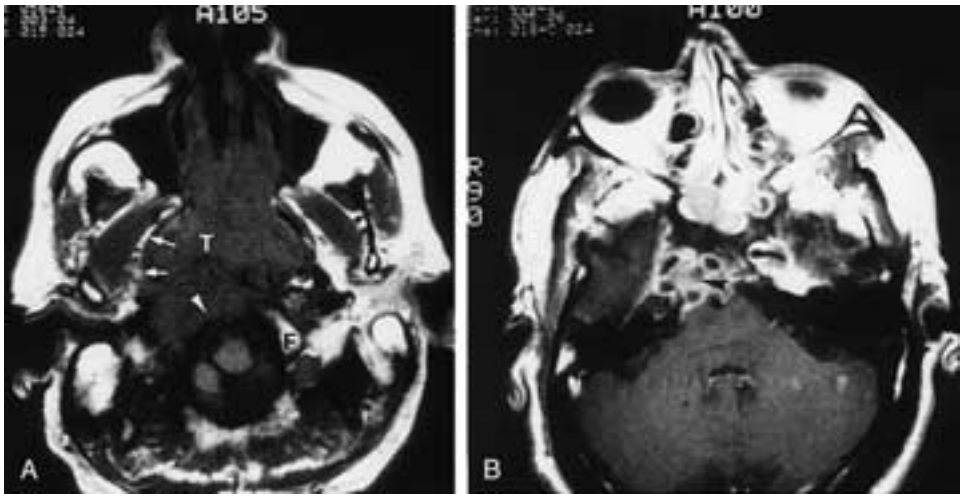
Perineural Spread

Tumor can selectively follow a nerve or the sheath of a nerve to reach and ultimately pass through a foramen of the skull base.[145–148] Adenoid cystic carcinoma has a strong propensity for this type of spread. Other malignancies such as lymphoma, melanoma, and even squamous cell carcinoma have shown this type of tumor extension. The trigeminal nerve and its branches travel from the brainstem to many areas of the face, sinuses, and oral cavity, and this nerve is a primary route for perineural spread of tumors of the head and neck. The auriculotemporal nerve, a branch of the third division (V_3), can carry tumor from the parotid gland to the main trigeminal nerve and through the foramen ovale to reach the cavernous sinus.[149] Tumors from the palate, sinuses, and face can follow the second division (V_2) to the pterygopalatine fossa and then through the foramen rotundum.[150] Perineural spread along the first division (V_1) is less common, but occasionally a lacrimal gland or skin malignancy can extend along this nerve through the superior orbital fissure. As tumor follows the nerve, the nerve and foramen usually enlarge (Figs. 12-89 and 12-90). Less commonly, tumor may extend along a nerve without causing enlargement, and skip areas of tumor along the nerve can occur with adenoid cystic carcinoma.[1]

Enhancement of a normal-sized nerve on a gadolinium-enhanced MR image is considered suggestive of perineural tumor spread. However, neuritis or secondary edema also may cause nerve enhancement. Usually, once the tumor has passed intracranially through a neural foramen, the tumor enlarges, now free from the restriction of the canal.

A key concept in assessment of possible perineural extension relates to the presence of fat at the extracranial opening of the various neural foramina.[152] Each of the major neural trunks or branches that may serve as a pathway for perineural spread emerges from the skull base into a variable amount of fat, and effacement or obliteration of this fat suggests the presence of tumor. Conversely, if the fat at the appropriate location is normal, the presumption is that the tumor has not reached the skull base. This can be an important factor in planning potential surgery.

One of the most important perineural pathways to and through the central skull base is the second division of the trigeminal nerve (Fig. 12-17). The maxillary division of the trigeminal nerve passes through the foramen rotundum to reach the pterygopalatine fossa. Here the main trunk divides into the infraorbital, palatine, and superior alveolar branches, traveling to the anterior face, posterior hard palate, maxillary sinus, and maxillary teeth, respectively. The palatine nerves are particularly important because the mucosa covering the posterior hard palate contains a large concentration of minor salivary glands. Adenoid cystic carcinoma, with its propensity to spread along nerves, is a common occurrence in this location. If tumor follows the palatine nerves to the pterygopalatine fossa, the fat within the fossa is obliterated (Figs. 12-89, 12-91, and 12-92).



VIEW IMAGE

FIGURE 12-87 Nasopharyngeal carcinoma invading the basiocciput. **A**, The tumor (*T*) expands outward. There is a smooth expansion (*arrowheads*) of the wall of the nasopharynx without extension into the parapharyngeal fat. This demonstrates the strength of the fascial layers. Even though the tumor did not extend through the fascia, there is invasion of the bone (*arrowhead*), and there is obliteration of the fat within the medullary cavity and absence of the cortex. Compare this with the fat (*F*) in the occipital condyle on the normal side. MR imaging is very sensitive to tumor extension through the medullary fat. Small cortical erosions, however, can be missed. **B**, Postgadolinium image shows tumor extension (*arrowhead*) through the petrooccipital fissure at the lateral aspect of the sphenoid bone. Although enhancement can obscure the margins of the tumor below the skull base, it is helpful in demonstrating the tumor extent relative to the cavernous sinus and dural margin.

VIEW IMAGE

FIGURE 12-88 A 12-year-old male presents with restriction of ocular motion and nasal stuffiness. Rhabdomyosarcoma of the nasopharynx with extension through the skull base. Coronal T1-weighted image shows the presence of a mass within the nasopharynx (*large asterisk*), with skull base destruction and invasion of the left cavernous sinus (*small asterisk*). Note the lateral deviation of the lateral dural reflection of the cavernous sinus (*curved arrow*). The mass abuts the cavernous internal carotid artery (*small arrows*). (From Braun IF. MRI of the nasopharynx. Radiol Clin North Am 1989;27(2):315.)

From this fossa, tumor can follow nerves through the foramen rotundum and Vidian canal to the region of the cavernous sinus.

The trigeminal nerve exiting the foramen ovale passes into a small amount of fat in the upper masticator space just medial to the lateral pterygoid muscle (Fig. 12-73). If tumor follows the auriculotemporal nerve from the parotid gland to the foramen ovale, this fat is obliterated. This pathway is a significant problem, as the tumor may not yet be palpable and the finding can be quite subtle. The patient typically presents with facial pain, as the sensory branches of the trigeminal nerve are involved.

Tumor following branches of the trigeminal nerve may reach the lower lateral aspect of Meckel's cave in the region of the Gasserian ganglion. Normally, there is slight enhancement of the periganglionic venous plexus, giving the appearance of a thin V. The V appears to thicken as tumor enlarges (Fig. 12-89).[153] Finally, the tumor can grow posteriorly from the cavernous sinus, following the preganglionic fibers of the trigeminal nerve toward the brainstem.

Typically, perineural spread occurs in a retrograde manner, toward the brain. However, antegrade spread can occur from branch points. For example, a tumor of the hard palate with retrograde perineural extension can reach the pterygopalatine fossa. From there, the malignancy can spread in an antegrade manner along the infraorbital nerve and spread in a retrograde pathway through the foramen rotundum. Similarly, once tumor has reached Meckel's cave, it can pass back out of the skull in an antegrade fashion through the foramen ovale into the masticator space. The topic of perineural tumor spread is also covered in Chapter 13.

Hematogenous Metastasis

Hematogenous metastasis can reach the basicranium from primary tumors in the lung, kidney, breast, prostate, and a variety of other, more rare locations. The imaging findings are usually those of lytic destruction. Apparent bone expansion rarely can occur in tumors originating in the thyroid or the kidney. Sclerotic changes may be present in prostate metastasis and rarely with squamous cell carcinomas, giving an appearance much like that of a meningioma. Any part of the sphenoid bone may be involved. If the greater wing of the sphenoid is affected, the metastasis tends to grow outward in all directions. Thus, tumor is seen along the lateral wall of the orbit, along the dura of the middle cranial fossa, and elevating the temporalis muscle away from the destroyed calvarium (Fig. 12-93). A meningioma can give a similar appearance.

TRAUMA

Though the sphenoid and basiocciput are substantial bones, fractures are not uncommon.[154–157] Such fractures are almost always associated with other severe facial bone, cranial vault, and skull base fractures. Of the various

Copyright © 2003, Mosby, Inc. All rights reserved.

elements of the skull base, the orbital roofs, temporal bones, and posterior basiocciput are more likely to be fractured than the more central basicranium.[156] Any of these fractures should be carefully followed to determine if they extend into the more central skull base. Of particular concern are fractures of the temporal bone, as they frequently extend obliquely into the lateral wall of the cavernous sinus, where they can injure the carotid artery.

Fractures of the central basicranium can compromise the numerous neurovascular structures traversing the bone (Fig. 12-94). In addition, muscles of ocular motion, mastication, and eustachian tube function attach to the sphenoid bone,

The pterygopalatine fossa (*black arrowhead*) is normal. **C**, Coronal T1-weighted postgadolinium image shows the perineural extension at the level of the cavernous sinus (*white arrowhead*), the foramen ovale (black *O*), and beneath the foramen ovale (*black arrowhead*). Note that the enlarged nerve is just at the medial margin of the lateral pterygoid (*LP*). The normal appearance of the foramen ovale is shown on the opposite side (white *O*).

VIEW IMAGE

and separation of the attachments of these muscles can result in functional deficits. The thinner plates of bone such as the greater wing of the sphenoid and the pterygoid plates offer less resistance to fracture, and unless significantly displaced, these fractures can be inconsequential. Although dysfunction of the attached muscles can cause problems in mastication, frequently the patients are asymptomatic. Significant inward displacement of a fracture of the greater wing can tear the dura and traumatize the brain.

The pterygoid processes of the sphenoid bone represent the posterior supporting strut of the facial skeleton. As such, the pterygoid plates are involved in the Le Forte fractures, separating the facial bones from the skull base. These fractures are discussed in Chapter 7. Fractures that do involve the sphenoid body and basiocciput place the numerous traversing neurovascular structures at risk, because the various neural foramina represent weak points in the bone, and the nerve within may be crushed, contused, or lacerated. A displaced bone fragment may also impinge upon the nerve.

Any of the nerves can be involved, and ophthalmoplegia or paresthesias can be the sequelae. Severe trauma can result in the superior orbital fissure syndrome, including a dilated pupil, ptosis, and extraocular muscle dysfunction. The optic nerve is of particular concern, and in a patient with vision loss after trauma, the optic canal must be carefully examined (Fig. 12-95). Any fracture of the orbital roof or of the lamina papyracea should prompt careful analysis of the optic canal. A displaced fragment may put pressure on the nerve, and if it is not quickly corrected, permanent visual loss will result. Immediate loss of vision can represent either actual nerve injury or nerve compression.[158] On the other hand, a delayed

FIGURE 12-91 *Continued.* **E**, Coronal MR T1-weighted postgadolinium image shows the enlargement of the second division of the trigeminal nerve just posterior (*white arrowhead*) to the foramen rotundum. The nerve is enlarged and enhances, indicating tumor involvement. **F**, Coronal bone algorithm shows enlargement of the foramen rotundum (*black arrowhead*) and the Vidian canal (*open black arrow*). This indicates tumor extension along both nerves. **G**, Enlargement of the lower pterygopalatine canal (*black arrowhead*), which connects the pterygopalatine fossa with the hard palate.

onset or progressive loss of vision usually represents an accumulating hematoma or edema. The optic nerve and optic canal can be visualized by axial and coronal CT. Identification of small fracture lines requires high-resolution, thin slices using bone algorithms. Because an orbital hematoma also can affect the optic nerve, the soft tissues should be carefully examined.

Fractures crossing the course of the carotid artery and involving the bone contiguous to the artery may or may not injure the wall of this vessel. These fractures can affect the thin, bony wall of the lateral sphenoid sinus at the indentation caused by the segment of the artery entering the cavernous sinus or they can be associated with fractures of the area of the anterior clinoid. Significant tears can result in death or in a carotid cavernous (CC) fistula (Fig. 12-96). In CC fistula, CT and MR imaging may show enlargement of the venous structures extending away from the cavernous sinus. Streaky reticulation of the orbital fat due to edema is usually seen, as well as the enlargement of the venous structures.

A fracture of the sphenoid bone can create a connection between the CSF spaces and the sphenoid sinus, resulting in a CSF leak, demonstrable by cisternography (Fig. 12-97). Such a communication can lead to meningitis, which is often delayed in onset. As stated, fractures of the sphenoid are often associated with other fractures of the skull or the skull base. Anosmia, periorbital ecchymosis (''raccoon eyes''), hemotympanum, or mastoid region ecchymosis (Battle's sign) may be seen in conjunction with findings related to the central skull base.

Dysplasias

The basicranium develops primarily through enchondral bone formation. As such, the central skull base can be involved by any generalized disorder that affects cartilaginous bone formation. Many of the findings are incidental. However, bony enlargement, characteristic of some dysplasias, and bone softening, characteristic of others, can lead to

VIEW IMAGE

significant problems resulting from compression of various cranial nerves or even of the brainstem and spinal cord. The base of the skull also is affected by generalized metabolic and hematologic diseases in which there are diffuse changes throughout the bony skeleton. Many of these entities cause softening of the bone, leading to a lack of support for the cranium. This can result in a protrusion of the upper spine into the foramen magnum or in a flattening of the skull base itself. These phenomena are referred to respectively as basilar invagination and platybasia.

Platybasia Versus Basilar Invagination

Platybasia and basilar invagination are terms used to characterize certain findings in patients with abnormal bony architecture of the basicranium. Although platybasia and basilar invagination may occur together, they represent different changes in the skull base. Platybasia is a flattening of the skull base. The basal angle of Weneke is the angle formed between a line drawn from the nasion to the center of the sella turcica and a line drawn from the center of the sella turcica down along the posterior aspect of the clivus. The normal adult basal angle is about 140°. If this angle is significantly increased, platybasia is present.

More frequently, the skull base softens and the upper cervical spine appears to push up into the base of the skull. Actually, the skull base is settling down around the focal pressure of the spine. This is true basilar invagination. There are several reference lines, developed to assess possible basilar invagination on plain films, that can be applied easily to midline sagittal MR imaging.

Chamberlain's line extends from the posterior margin of the hard palate to the posterior margin of the foramen magnum. If the tip of the odontoid is 5 mm or more above this line, basilar invagination is present. At times, the lip of the occipital bone, which makes up the posterior margin of the foramen magnum, is difficult to visualize on the lateral radiograph. To deal with this problem, McGregor's line was developed, extending from the posterior margin of the hard palate to the most inferior point on the cortex of the occipital bone posterior to the foramen magnum. This point is much easier to see on the lateral radiograph. Using this system, basilar invagination is considered to be present if the tip of the odontoid is 7 mm above the line or if more than one third of the height of the

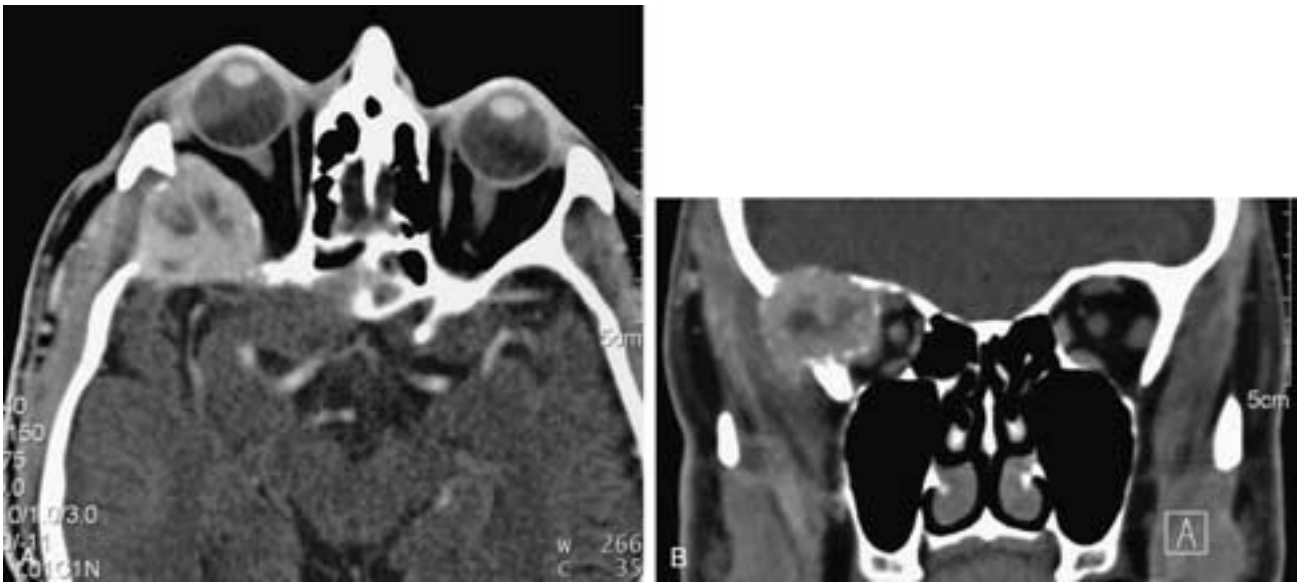

FIGURE 12-93 Metastatic renal carcinoma to the sphenoid triangle (greater wing of the sphenoid). **A**, The tumor is seen replacing the bone of the sphenoid triangle and extending into the orbit, temporalis fossa, and middle cranial fossa. **B**, Coronal CT postcontrast image.

FIGURE 12-94 A 23-year-old male following an automobile accident presents with superior orbital fissure syndrome and multiple cranial nerve deficits. Multiple skull base fractures. Axial CT scan through the skull base shows the presence of multiple fractures associated with fluid in the ethmoid and sphenoid sinuses. Multiple fractures causing narrowing of the orbital apex and inferior orbital fissure (*open arrow*) are appreciated, as well as a fracture involving the foramen ovale (*black arrow*).

odontoid process is above this line. Because on a sagittal MR image both the posterior lip of the foramen magnum and the lowest point on the occiput can be easily identified, either system can be used.

Although platybasia can occur in many situations, the findings are characteristic of abnormalities such as Paget's disease, osteogenesis imperfecta, and osteomalacia. These abnormalities are all associated with softened abnormal bone incapable of supporting the weight of the skull. On the other hand, basilar invagination has been reported in achondroplasia, ankylosing spondylitis, Arnold-Chiari malformation, atlantoaxial dislocation, cleidocranial dysplasia, congenital craniovertebral junction abnormalities, Crouzon's syndrome, Down's syndrome, familial primary basilar impression, fibrous dysplasia, Haju-Cherney syndrome, histiocytosis, chronic hydrocephalus, hyperparathyroidism, hypophosphatasia, Klippel-Feil syndrome, mucopolysaccharidosis, occipital craniotomy in a child, osteogenesis imperfecta, osteomalacia, osteomyelitis, osteopetrosis, osteoporosis, Paget's disease, pyknodysostosis, rheumatoid arthritis, rickets, and an unfused posterior arch of the atlas.[159]

Fibrous Dysplasia

Fibrous dysplasia is an abnormality of the bone with abnormal development of the fibroblasts and abnormal mineralization.[160–163] The bone is enlarged, and on CT, the cortex tends to be maintained and the enlarged medullary space can have a variety of appearances, depending on the amount of fibrous and osteoid matrix present. The appearance on CT varies from a fairly lucent medullary space to a densely calcified one. Some cases have a mixture of dense and sclerotic changes sometimes referred to as pagetoid. The

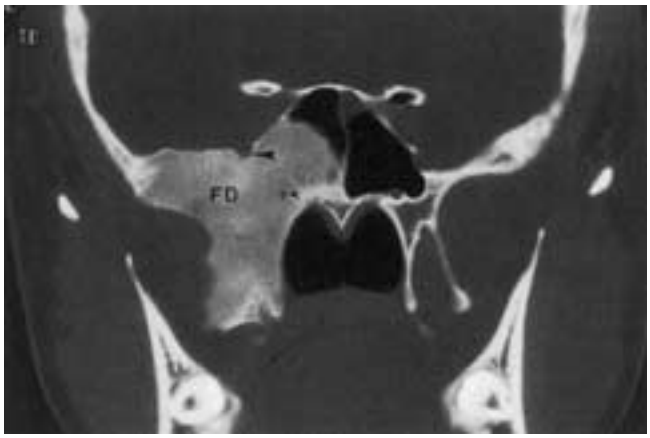
FIGURE 12-96 A 23-year-old male who presents with pulsatile exophthalmos and decreased visual acuity following a motorcycle accident. Skull base fracture with resultant cavernous carotid fistula. Lateral subtraction view of an internal carotid artery angiogram shows findings typical of a carotid cavernous fistula. Contrast from the arterial system has extravasated into the cavernous sinus (*large asterisks*) and subsequently into the superior ophthalmic vein (*small asterisks*). Arterial pressure transmitted to the venous system in the superior ophthalmic vein causes the pulsatile exophthalmos.



VIEW IMAGE

FIGURE 12-98 Fibrous dysplasia (*FD*) shows a typical ''ground glass'' appearance. The Vidian canal (*small black arrowhead*) and the groove for the second division of the trigeminal (*large black arrowhead*), just posterior to the foramen rotundum, have been incorporated or displaced by the expanding abnormality.

classic CT and plain film appearance is the ''ground glass'' medullary space surrounded by intact cortices (Fig. 12-98).

On MR imaging, the lesion has fairly low T1-weighted and T2-weighted signal intensity (Fig. 12-99). The internal matrix enhances with gadolinium, a phenomenon not as easily appreciated on CT. Although the classic appearance is one of a fairly homogeneous internal density on CT or signal intensity on MR imaging, inhomogeneous areas can be

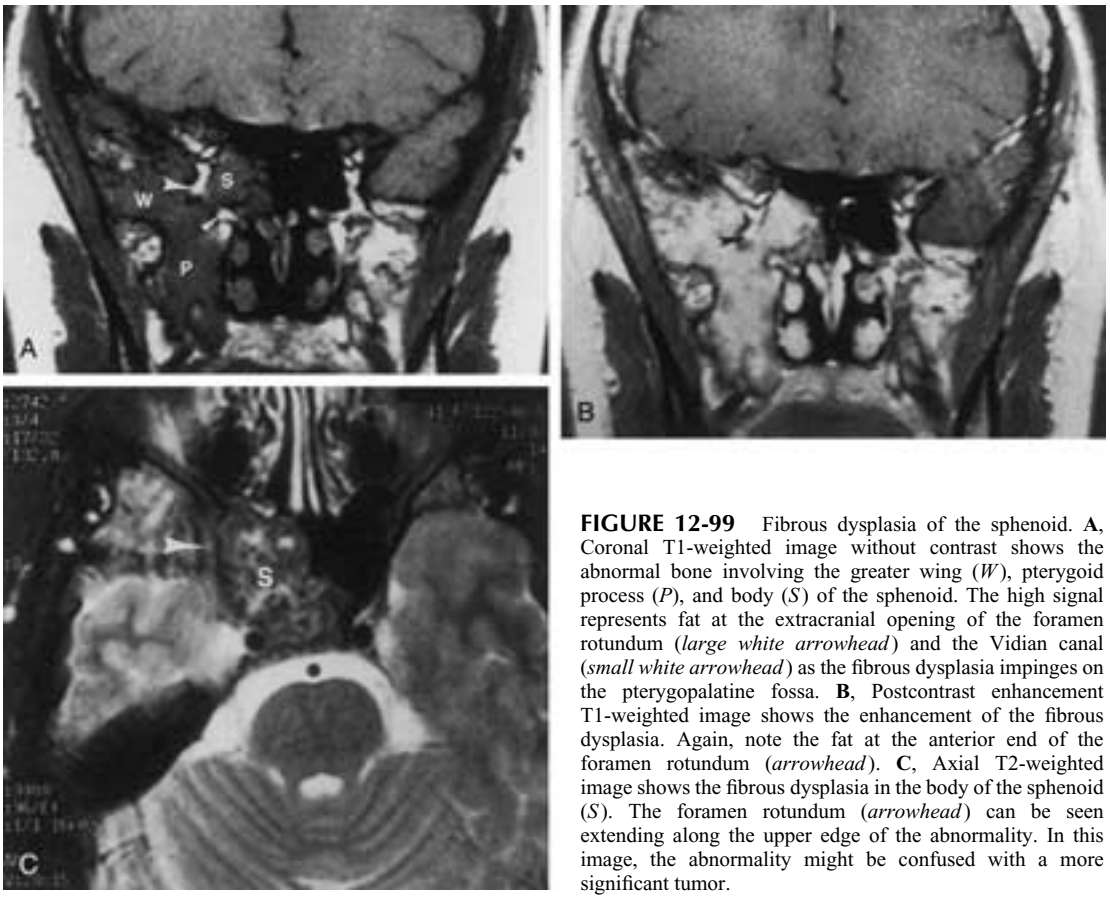

FIGURE 12-99 Fibrous dysplasia of the sphenoid. **A**, Coronal T1-weighted image without contrast shows the abnormal bone involving the greater wing (*W*), pterygoid process (*P*), and body (*S*) of the sphenoid. The high signal represents fat at the extracranial opening of the foramen rotundum (*large white arrowhead*) and the Vidian canal (*small white arrowhead*) as the fibrous dysplasia impinges on the pterygopalatine fossa. **B**, Postcontrast enhancement T1-weighted image shows the enhancement of the fibrous dysplasia. Again, note the fat at the anterior end of the foramen rotundum (*arrowhead*). **C**, Axial T2-weighted image shows the fibrous dysplasia in the body of the sphenoid (*S*). The foramen rotundum (*arrowhead*) can be seen extending along the upper edge of the abnormality. In this image, the abnormality might be confused with a more significant tumor.

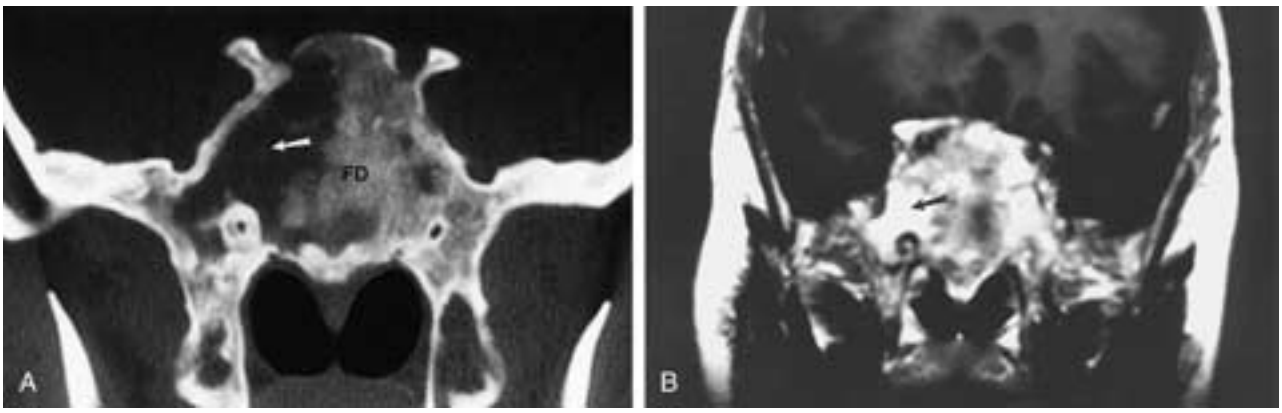
VIEW IMAGE

present.[164] Some areas may be predominantly fibrous tissue with the appropriate CT and MR imaging findings. Some areas may represent hemorrhage and cyst formation. In the central skull base, parts of the sphenoid sinus may become isolated and obstructed. The trapped secretions can give signal intensities similar to those of the inhomogeneities of the fibrous dysplasia itself (Fig. 12-100). This can be of concern if the patient is evaluated for pain, as early mucocele formation cannot be differentiated from a static cystic region in fibrous dysplasia. Increasing size suggests mucocele formation. Most of the mineralized matrix is considered to be immature woven bone. Occasionally, small amounts of cartilage formation can occur, but this is unusual (Fig. 12-101).



VIEW IMAGE

FIGURE 12-100 Fibrous dysplasia **A**, Fibrous dysplasia with low-density area on CT. The fibrous dysplasia (*FD*) fills and expands most of the body of the sphenoid. There are areas of low density (*arrow*), which could represent either cystic components of the fibrous dysplasia or areas of obstructed secretions because of the sinus mucosa. **B**, Coronal T1-weighted MR image shows high signal intensity consistent with the cystic portion of the fibrous dysplasia. However, note that this area extends between the Vidian canal and the foramen rotundum, which would be the usual position of a laterally extending air cell.

FIGURE 12-101 **A**, Fibrous dysplasia with secondary osteosarcoma. Fibrous dysplasia (*FD*) involves the greater wing of the sphenoid, extending into the sphenoid bone and including the lesser wing. It is bilateral. The sarcoma (*S*) is seen in the region of the nasal cavity extending into the orbit. **B**, More inferior scan shows the sarcoma (*S*) in the anterior nasal cavity. This fibrous dysplasia has small areas of cartilage formation histologically. This is shown as small rings of calcification (*open arrow*) on the CT scan.

Paget's Disease

Paget's disease is a process of unknown cause in which osteoclastic activity is abnormal.[165] The normal osseous structure is replaced by an abnormal matrix that is more vascular than normal. The osteoblasts continue to respond to this abnormal situation and lay down a thicker, more sclerotic, but softer bone. This bone involves the cortex and the trabeculae within the medullary cavity, and there is poor corticomedullary differentiation. There is more bone than usual, and the bone can be dense or lucent (Fig. 12-102). The findings in the temporal bone appear to be primarily lytic because they involve and demineralize the otic capsule. Again, because the bone is softer than normal, basilar invagination is frequently present. In this disease, the remodeling of the softened bone may be so extensive that there is true platybasia and basilar invagination. Secondary sarcoma canl occur.[166]

Bone Dysplasias, Mucopolysaccharidosis, and Metabolic Diseases

Many of the bone dysplasias cause abnormal density and shape of the skull base.[167, 168] Terminology varies, but this group of lesions includes the various osteochondrodysplasias, dysostoses, and osteopetroses.[160] Basilar invagination, though occurring occasionally, is not a typical finding in many of these bone disorders because the abnormal bone is not particularly soft. The distribution and appearance of the findings in the long bones and the craniofacial skeleton are used to establish the diagnosis. Thickening of the bone may take place at the expense of the neural foramina (Fig. 12-103), and cranial nerve palsies can result.[169, 170] Involvement of the sphenoid bone can lead to blindness or various ophthalmoplegias. Temporal bone involvement can lead to deafness and facial nerve paralysis.

Achondroplasia is an abnormality that affects the development of enchondral bone, and thus the skull base is predictably involved. The failure of growth at the sphenooccipital synchondrosis leads to a short clivus and a smaller sphenoid bone. The floor of the posterior fossa is higher and more horizontal than normal, with variable narrowing of the foramen magnum. If pronounced, this can lead to severe neurologic problems. A typical J-shaped sella is an incidental finding. Platybasia occurs because of maldevelopment of the occipital vertebral junction.

Osteogenesis imperfecta causes a deficient, weakened

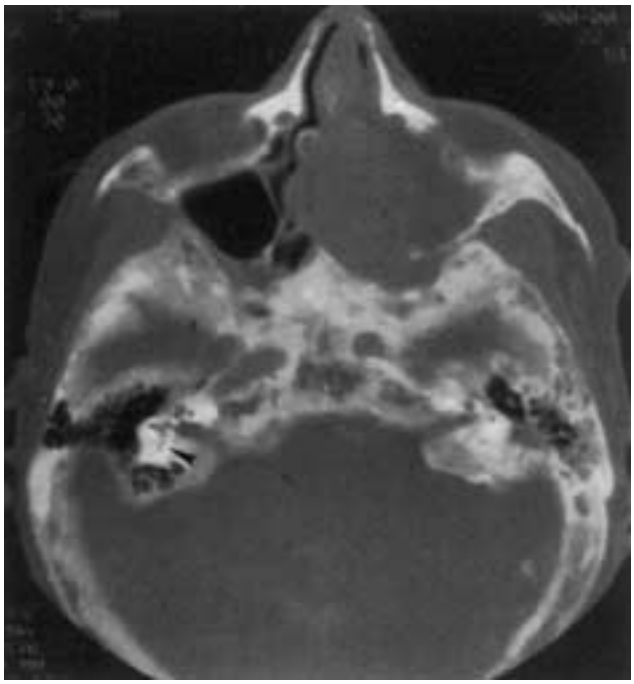

FIGURE 12-102 Paget's disease of the skull base. The diffuse, abnormally mineralized bone is seen in the temporal bone and sphenoid. There is relative sparing but some demineralization of the otic capsule (*arrowhead*). The patient had a sarcoma in the region of the maxillary sinus and nasal cavity.

VIEW IMAGE

bone structure, and basilar invagination occurs. The severity is quite variable in the tarda form. Wormian bones and narrowing of the foramen magnum also are present. The temporal bone can be involved with what appears to be extensive otosclerosis and production of undermineralized bone around the labyrinth.

The mucopolysaccharidoses (Morquio's, Hurler's, Hunter's, Maroteaux-Lamy, etc.) are lysosomal storage diseases. The skull base shows abnormal growth, and again, a J-shaped sella is present. The bone of the skull base may be thicker than usual, but because the bone is abnormal, basilar invagination can be present. Associated craniovertebral anomalies, with atlantoaxial instability, are considered more significant problems and can lead to severe neurologic deficits.

Hyperparathyroidism and other metabolic diseases also can result in an abnormal skull base with softening of the normal bone. However, the diagnosis usually is known or is made by evaluation of other parameters.

CEREBROSPINAL FLUID LEAK

A CSF leak may either be related to trauma, with a fracture creating the communication between the CSF space and the sinonasal cavities (Fig. 12-97), or may occur spontaneously.[171] The patient may present with clear rhinorrhea that is evident when the patient bends forward. Alternatively, the patient may swallow the CSF. Meningitis or intracranial abscesses may occur because the communication becomes an entrance pathway for microorganisms found in the sinonasal tract. The most common site of CSF

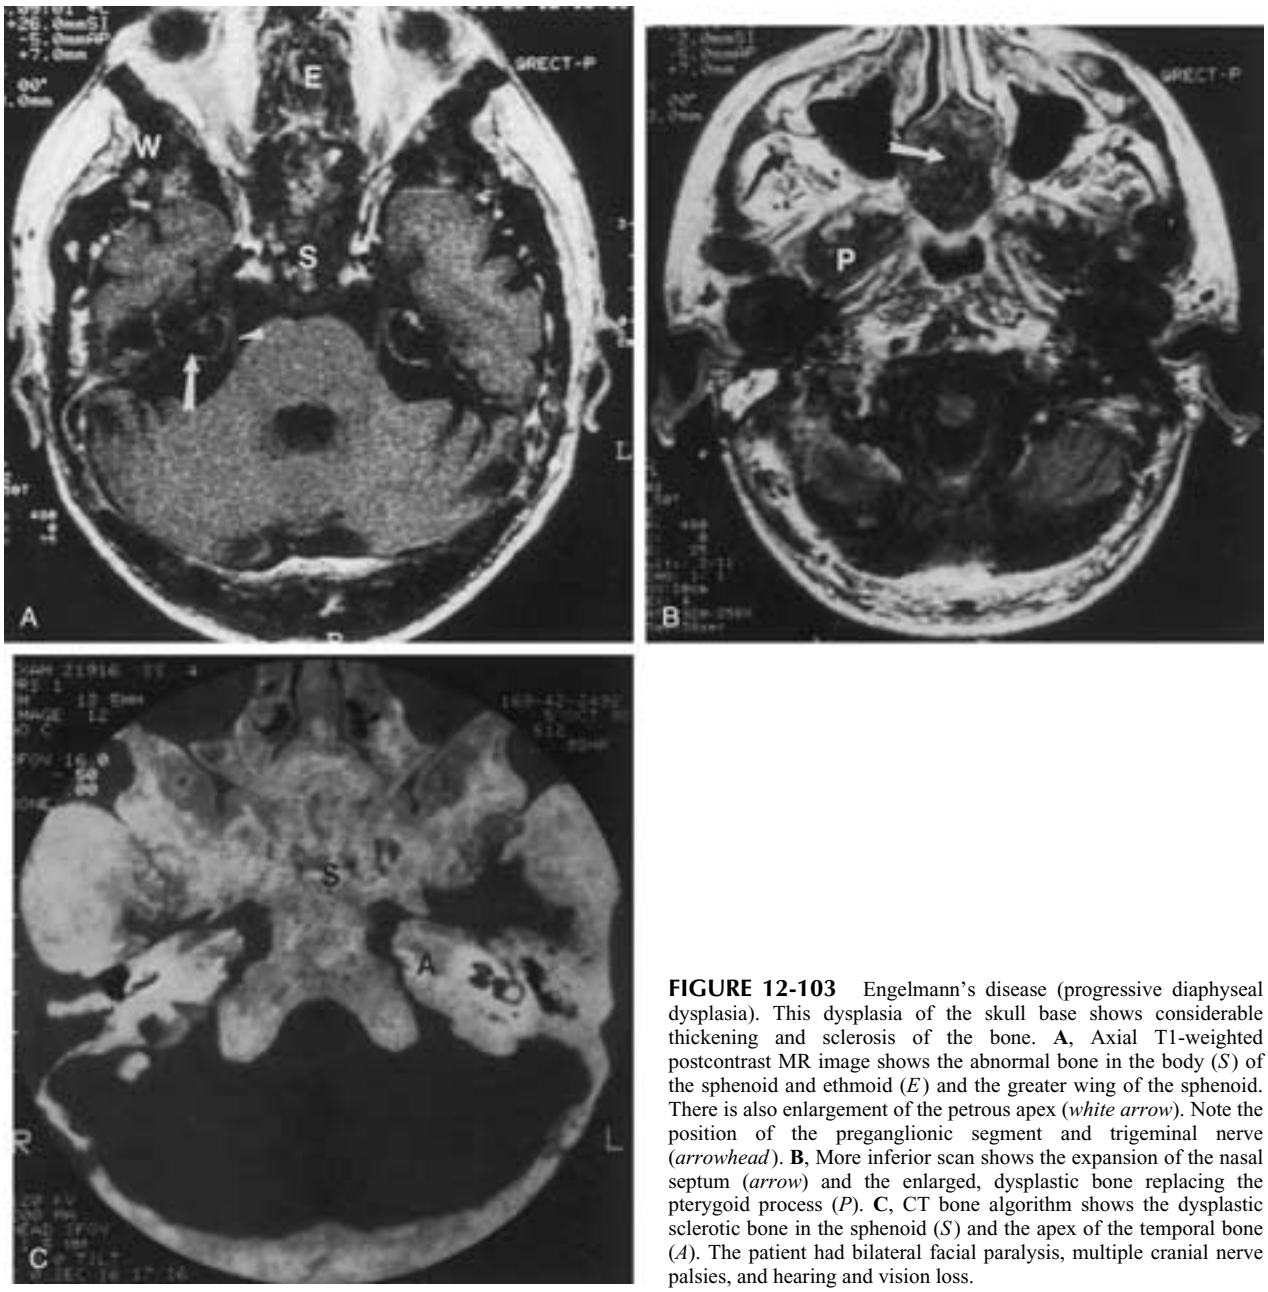

FIGURE 12-103 Engelmann's disease (progressive diaphyseal dysplasia). This dysplasia of the skull base shows considerable thickening and sclerosis of the bone. **A**, Axial T1-weighted postcontrast MR image shows the abnormal bone in the body (*S*) of the sphenoid and ethmoid (*E*) and the greater wing of the sphenoid. There is also enlargement of the petrous apex (*white arrow*). Note the position of the preganglionic segment and trigeminal nerve (*arrowhead*). **B**, More inferior scan shows the expansion of the nasal septum (*arrow*) and the enlarged, dysplastic bone replacing the pterygoid process (*P*). **C**, CT bone algorithm shows the dysplastic sclerotic bone in the sphenoid (*S*) and the apex of the temporal bone (*A*). The patient had bilateral facial paralysis, multiple cranial nerve palsies, and hearing and vision loss.

VIEW IMAGE

FIGURE 12-104 CSF leak into an enlarged sphenoid sinus. **A**, Axial T1-weighted image shows low signal equivalent to CSF in an expanded sphenoid sinus. The lateral extent of the sinus extends into the medial greater wing at the attachment of the pterygoid process. **B**, Axial T2-weighted image shows high signal compatible with CSF. **C**, Axial CT image prior to injection of intrathecal contrast shows a small pit (*arrow*) along the anterior wall of the middle cranial fossa. A small defect (*arrowhead*) appears to extend into the cystic cavity. This may represent extension of arachnoid granulations or a small fracture at that site. **D**, Postintrathecal contrast image shows filling of the cystic cavity as well as the prepontine cistern and fourth ventricle.

breech is anteriorly through the region of the cribriform plate or ethmoid roof. The second most common site is the temporal bone, where fractures may be associated with a CSF leak. If the tympanic membrane is ruptured, the fluid passes out into the external auditory canal as otorrhea. If the membrane is intact, the fluid passes through the eustachian tube into the nasopharynx and posterior nasal cavity. The patient can present with rhinorrhea, mimicking a fracture of the anterior skull base, and sphenoid sinus fluid levels, suggesting a fracture of the sphenoid sinus walls. CSF leaks through fractures of the sphenoid bone, communicating with the sphenoid sinus, are uncommon but do occur. The fracture must connect the sphenoid sinus and the CSF space, and so the location is usually over a lateral air cell at the root of the pterygoid process or in the floor of the middle cranial fossa. Here the cavernous sinus does not cover and ''protect'' the sinus. Of course, fractures through the sinus roof, especially if there is also an ''empty'' sella, can cause a CSF leak.

Tumors, especially those arising in the pituitary gland, can cause a nonsurgical CSF leak. Encephaloceles and congenital anomalies also rarely are responsible for CSF rhinorrhea. Spontaneous CSF rhinorrhea can pass along a communication through the anterior wall of the middle cranial fossa into a lateral air cell in the root of the pterygoid process or greater wing of the sphenoid.

Arachnoid granulations frequently are found in the anterior wall of the middle cranial fossa. A small defect in the dura can complete the communication through the thin bone. The communication is typically from the CSF space into the lateral or pterygoid air cell of the sphenoid sinus. This is the air cell protruding laterally between Vidian's canal and the foramen rotundum into the attachment of the pterygoid process. The CSF flows out through the sphenoid ostium into the posterior nasal cavity. Due to the pulsatile pressure of the CSF, an affected air cell may expand, mimicking a mucocele (Fig. 12-104).

CSF fistulas may be seen after skull base surgery.

Copyright © 2003, Mosby, Inc. All rights reserved.

Considerable effort is put into preventing this complication. One of the primary goals of reconstructive flap design is isolation of the CSF and the intracranial structures from the external world, particularly the sinonasal tract, with its plethora of potential pathogens. However, the pulsating pressure of the CSF works against the surgeon, and leaks occasionally occur. Because of the distorted postoperative anatomy, collections within the soft tissues or grafts may occur. These pseudomeningoceles may be clinically inconsequential if small, but they must be surgically corrected if large. The radiologic evaluation is done with CT or MR imaging. In the postoperative case, the area of primary concern is obvious, but the identification of the defect in the skull base often is not specifically useful because large defects are routine. Very useful is the identification of a fluid collection in the contiguous soft tissues or an intracranial air bubble near the site of the leak.

In the nonoperated patient, high-resolution CT is performed with a bone algorithm to look for a bony dehiscence.[172] Even if a defect is not seen, a collection of fluid within a sinus may suggest the location of the leak. Because the middle ear and mastoid are potential sites for the CSF leak, these areas must be carefully examined. In either the operated or the nonoperated patient, if the leak is not obvious, intrathecal contrast can be used. The patient is placed in the position that clinically is related to the CSF leak, and further CT imaging is done.[172, 173] Contrast cisternography is unlikely to be successful unless an active leak exists at the time of the study.

Radionuclide cisternography is considered to be more sensitive than these studies, but it does not accurately localize the leak site. The radionuclide is injected intrathecally, and pledgets are placed in the areas most likely to detect a leak (i.e., the pledgets may be placed high in the nasal cavity by the otolaryngologist). Later, the pledgets are retrieved and measured for radioactivity. Although this procedure can be done to confirm that a leak is present, it requires an active leaking at the time of the study. Recently, clinicians have been better able to verify that the rhinorrhea fluid is indeed CSF by testing the fluid for beta 2-transferrin, which is present in CSF but not in sinonasal secretions.

VIEW IMAGE

FIGURE 12-105 Radiopaque foreign body from glycerol rhizotomy. The radiopaque material (*large black arrowhead*) was added to the alcohol, which was injected into the area of Meckel's cave in the hope of relieving facial pain. The nerve (*small black arrowhead*) can be seen surrounded by this contrast.

RHIZOTOMY INJECTIONS

In order to control pain, alcohol may be injected into the Gasserian ganglion. Radiopaque material is often mixed with the injected alcohol. This appearance is characteristic and should not be confused with a calcified neoplasm (Fig. 12-105). The material is injected via the foramen ovale and can follow the nerve or can track along the dura.

PERSISTENT POSTTREATMENT IMAGING ABNORMALITIES
MIMICS OF PNS
CONCLUSION

INTRODUCTION

In malignancies of the head and neck, tumor may spread along the neural sheath (via the endoneurium, perineurium, or perineural lymphatics) by a process known as perineural tumor spread (PNS). PNS most commonly occurs in a retrograde direction, toward the central nervous system, but also can occur in an antegrade manner. Early in the twentieth century there were scattered reports of this phenomenon.[1] The first comprehensive report on PNS was the frequently referenced work by A.J. Ballantyne et al., while in the imaging literature, the landmark article was by Dodd et al., who reported the plain film imaging findings in 40 patients.[2, 3] Despite the fact that PNS is well known, it remains a vexing clinical problem because it may be clinically silent and because it is often missed at imaging.

PERINEURAL INVASION VERSUS PERINEURAL SPREAD

It is important to distinguish between perineural invasion and perineural spread, as there is some confusion in the literature concerning the use of the term *perineural*. Perineural *invasion* is the microscopic finding of tumor cells surrounding very small nerve branches, and as such it cannot be seen on imaging.[4] It is an ominous prognostic sign associated with an increased local recurrence rate and decreased survival.[5, 6] This chapter is concerned with macroscopic or large nerve PNS, in which there is gross tumor spread, sometimes over a considerable length of the nerve.

Since PNS may be asymptomatic, it is critical that radiologists be vigilant in their efforts to detect it prior to the institution of therapy. The finding of PNS may convert a

lesion thought to be resectable into a nonresectable one. The presence of PNS may also mean that radiation fields need to be expanded to encompass the tumor spread. In the case of a parotid tumor, the finding of PNS may indicate that a temporal bone resection with a partial facial nerve resection may be needed to ensure a tumor-free margin along the facial nerve.

As mentioned, failure to diagnose PNS may have grave implications, particularly if the mode of therapy fails to address the disease extension along the nerve. Such failure virtually guarantees a tumor recurrence, which actually represents a progression of undetected residual disease. Furthermore, failure to recognize PNS on imaging studies is a not infrequent cause of legal action against radiologists. Reasons for failing to diagnose PNS include lack of familiarity with the types of cancers that commonly are associated with it, lack of familiarity with the common routes and imaging appearance of PNS, and inadequate imaging.

THE MOST COMMON ANATOMIC LOCATIONS AND TUMOR HISTOLOGIES ASSOCIATED WITH PNS

Though virtually any head and neck malignancy may be associated with PNS, certain primary sites and cancer types are clearly more likely to spread along the perineural route. Cutaneous malignancies, particularly squamous cell carcinomas and desmoplastic melanomas, tend to be associated with PNS, and such tumor spread is often associated with a recurrence of skin cancer.[6–10] Although these tumors may occur anywhere on the face, there is a predilection for the side of the nose and the lower lip, areas supplied by the maxillary division of the trigeminal nerve (V_2).[11, 12]

Mucosal primaries such as squamous cell carcinoma and especially minor salivary gland cancers such as adenoid cystic carcinoma are also associated with PNS.[13–16] In particular, primary tumors in the palate may gain direct access to the palatine nerves that innervate these mucosal surfaces, while nasopharyngeal tumors may spread to V_2 via extension into the pterygopalatine fossa (PPF) or to V_3 via extension into the masticator space.[13, 14, 17]

Virtually any salivary gland cancer, especially those arising in the parotid gland, may be associated with PNS. In such cases, although the facial nerve is at greatest risk for PNS, the auriculotemporal branch of the mandibular nerve may also provide a route for PNS.[13, 18] Another clinical setting involving the parotid gland that may result in PNS is either direct tumor extension or intraparotid metastases from an adjacent primary or recurrent skin cancer.[13, 19]

In addition to the cancers just mentioned, other malignancies, regardless of their histology or primary location, may also be associated with PNS if they involve anatomic sites such as the masticator space, PPF, or cavernous sinus/Meckel's cave.[13] For reasons that are unclear, cancers in certain locations do not often spread along perineural pathways. These sites include the submandibular gland, tongue, buccal mucosa, tonsil, larynx, pharynx, and floor of the mouth. Exceptions at these locations may occur, particularly if the tumor has extended to one of the areas mentioned that are associated with PNS.

SIGNS AND SYMPTOMS ASSOCIATED WITH PNS

The signs and symptoms most commonly associated with PNS include pain, paresthesias, numbness, formication (the sensation of ants and worms under the skin), and motor denervation weakness. The last is most often encountered as either facial paralysis or masticator muscle weakness when the facial nerve and V_3, respectively, are involved.[13, 19] Although microscopic perineural invasion may have similar symptoms, PNS should be considered when the neurologic symptoms suggest broader involvement than would be expected based on the location of the lesion (e.g., a small facial skin cancer with multiple divisions of the affected trigeminal nerve). Multiple cranial neuropathies are also an ominous finding, suggesting either PNS proximal to the cavernous sinus, tumor spread from one cranial nerve to another, or leptomeningeal disease.[7, 11] While the above-mentioned symptoms may suggest PNS, up to 40% of patients with PNS have either nonspecific symptoms or are asymptomatic.[7, 19, 20–22]

COMMON CLINICAL SETTINGS ASSOCIATED WITH PNS

In addition to the presence of a primary tumor in a high-risk location, there are postoperative clinical settings that are associated with PNS. These include the development of a cranial neuropathy in a patient who has had a previously resected tumor, with or without an obvious local recurrence.[7, 10, 11, 22] A typical history is that of a previous resection of a skin lesion thought either to be benign or malignant (often the specimen is no longer available for review, and occasionally the patient may not remember the surgery) associated with a new neurologic deficit along the corresponding branch of the trigeminal nerve or a more generalized trigeminal neuropathy.[10] Another common scenario is the development of a facial nerve paralysis in a patient who has had a prior resection of a parotid mass. Such histories should prompt a careful imaging search for PNS, and it is important that these patients not simply be diagnosed as having ''Bell's palsy'' or ''trigeminal neuralgia'' until more sinister causes are excluded.[10]

Unfortunately, the radiologist may not be aware that a lesion was previously resected, and the appropriate history must be specifically sought. On the other hand, if a neurologic deficit was caused by therapy or the initial presentation of the primary lesion, the patient may not report any new symptoms. Thus, if parotidectomy resulted in a facial nerve palsy, postoperative imaging may be the only way to establish the presence of PNS prior to the onset of additional cranial neuropathies.

Lastly, though rare, evidence of PNS may present clinically prior to detection of the associated primary cancer.[23] This might occur with an asymptomatic, submucosal, slow-growing tumor such as an adenoid cystic carcinoma. Several such tumors arising in the palate with PNS to the cavernous sinus have been reported.[23] Thus, an important corollary in the setting of no known primary tumor is that any patient who presents with a mass

Copyright © 2003, Mosby, Inc. All rights reserved.

in one of the common proximal locations associated with PNS (the PPF, Meckel's cave, or the cavernous sinus) should have a careful clinical and radiologic evaluation for a primary clinically silent head and neck malignancy.

ANATOMIC NEUROLOGIC CONSIDERATIONS

The cranial nerves most often involved in PNS from head and neck cancer are the trigeminal and facial nerves.[13, 15] Rarely, spinal nerve branches may be affected. In order to recognize PNS when it is visible on imaging studies, the radiologist must be familiar with the cranial nerve anatomy, including the branches that innervate a particular head and neck location and the proximal course of those nerves.

Ophthalmic Division of the Trigeminal Nerve (V_1)

The ophthalmic division of the trigeminal nerve (V_1) is uncommonly affected by PNS.[24–26] This nerve provides purely sensory innervation to the eye, lacrimal gland, conjunctiva, part of the nasal mucosa, and skin of the nose, eyelids, forehead, and scalp.[27] Figure 13-1 depicts the anatomy of the ophthalmic nerve. After emerging from the Gasserian ganglion in Meckel's cave, the ophthalmic nerve courses through the cavernous sinus, passes through the superior orbital fissure to enter the orbit, and then divides into the nasociliary, lacrimal, and frontal nerves (Fig. 13-1).

The frontal nerve is the largest branch; it divides into a smaller supratrochlear branch and a larger supraorbital branch (Fig. 13-1). The supratrochlear nerve runs anteromedially and exits the orbit to provide cutaneous innervation to the medial supraorbital region and the lower forehead near the midline. Cutaneous cancers in this region may have PNS along the supratrochlear nerve (Fig. 13-2). The supraorbital nerve courses anteriorly between the levator palpebrae and the orbital roof and then exits the orbit, where it divides into medial and lateral branches (Fig. 13-1). These branches provides sensory innervation to the scalp in the immediate supraorbital region and as far back as the lambdoidal suture.[27] Small branches also supply innervation to the frontal sinus mucosa and the pericranium. The supraorbital nerve is also at risk for PNS when a skin cancer arises in its region of innervation.

The lacrimal nerve provides innervation to the lacrimal gland, having first received a twig from the zygomaticotemporal nerve, which is a small branch of V_2 (containing postganglionic parasympathetic innervation from the pterygopalatine ganglion, originating in the greater superficial petrosal nerve, a branch of the facial nerve).[27] The nasociliary nerve provides small branches that innervate the frontal dura and the nasoethmoid mucosa. While it is theoretically possible that cancers along the distribution of these nerves (lacrimal gland, nasoethmoid, etc.) could be associated with retrograde PNS, such cases have not been reported.

Maxillary Division of the Trigeminal Nerve (V_2)

The maxillary division of the trigeminal nerve (V_2) provides sensory innervation to the skin of the midface, the mucosa of the palate, sinonasal region, and maxillary gingiva, and the maxillary teeth. Figure 13-3 depicts the anatomy of the maxillary nerve. The maxillary nerve courses through the cavernous sinus and then through the foramen rotundum to enter the PPF. Within the PPF, the maxillary nerve gives rise to several palatine branches as well as the zygomatic nerve. The palatine nerves course inferiorly through the greater and lesser palatine foramina to innervate the hard and soft palates, respectively.[14] The zygomatic nerve enters the orbit through the inferior orbital fissure, runs along the lateral orbital wall, and divides into the zygomaticofacial and zygomaticotemporal branches.[27] The zygomaticotemporal nerve sends a small twig to the lacrimal nerve, as mentioned earlier. Both the zygomaticotemporal and zygomaticofacial nerves exit the orbit through its lateral wall and supply innervation to the skin of the temporal region and lateral cheek (Fig. 13-3).[27] Also within the PPF, the maxillary nerve gives off the posterior superior alveolar nerve to the maxillary sinus.

More distally, the maxillary nerve enters the infraorbital canal as the infraorbital nerve and gives off the anterior and middle superior alveolar nerves to the maxillary teeth and gingiva. The infraorbital nerve then emerges from the infraorbital foramen and divides into its terminal branches, supplying the skin of the midfacial region and lateral nose (Fig. 13-3). Proximal or retrograde PNS from any of these innervated sites can occur along the respective distal branches of V_2, generally eventually involving the PPF.[28] Thus, tumors arising in the cheek are at particularly high risk of PNS along the infraorbital nerve, often with tumor in the PPF (Figs. 13-4, 13-5).[6, 8, 10, 13, 22, 28]

Skin cancers in the temporal region and upper lateral face may spread to the orbit via the zygomatic nerve (Fig. 13-5). A palate lesion can spread along the palatine nerves and then to the PPF (Figs. 13-6, 13-7).[14] Maxillary sinus tumors may have PNS along the superior alveolar nerves to enter the PPF.[28] If a nasopharyngeal carcinoma has extended into the nasal cavity, it may spread laterally through the sphenopalatine foramen to enter the PPF (Fig. 13-8).[13, 17] Once in the PPF, retrograde PNS can occur along the main trunk of V_2 through the foramen rotundum, with subsequent involvement of the cavernous sinus and Meckel's cave or even the more proximal main trigeminal nerve trunk (Figs. 13-7, 13-8).[13, 15, 28]

Once tumor is in the PPF, PNS may also occur along the vidian nerve (or nerve of the pterygoid canal) (Fig. 13-9).[13, 14, 29, 30] Antegrade PNS may occur once the PPF is involved. Commonly this occurs along branches of V_2, especially the infraorbital nerve (Fig. 13-7C).[3, 13, 15, 28] Once tumor has spread into Meckel's cave, antegrade PNS may also occur along V_3 (Fig. 13-7D).

Mandibular Division of the Trigeminal Nerve (V_3)

The mandibular division of the trigeminal nerve (V_3) provides sensory innervation to the skin of the lower face

Tumor can be seen widening and replacing the expected hyperintense fat within the right PPF (*white dots*). Note the normal hyperintense fat in the left PPF (*black dots*). **B**, Coronal T1-weighted MR image shows a grossly enlarged right infraorbital nerve representing perineural spread (*arrowhead*). Note the right-sided tumor recurrence in the temporal region (*asterisks*). The lateral intraorbital mass (*arrow*) likely represents PNS along the zygomaticotemporal/zygomaticofacial branches of V_2 (see Fig. 13-3). (From Ginsberg LE. Imaging of perineural tumor spread in head and neck cancer. Semin Ultrasound CT MR 1999;2:175–186.)

and the preauricular/temporal region, the mandibular teeth, and the mucosa of the mandibular gingiva, floor of the mouth, the tongue (anterior two thirds), and the buccal mucosa.[27] The mandibular nerve also provides motor innervation to the muscles of mastication and the mylohyoid and anterior belly of the digastric muscles. Figures 13-3 and 13-10 depict the anatomy of V_3. Exiting Meckel's cave, the mandibular nerve avoids the cavernous sinus and courses inferiorly through the foramen ovale to enter the masticator space, where it divides into anterior and posterior trunks. The anterior trunk primarily gives rise to motor branches (for the masseter, temporalis, and pterygoid muscles). The posterior trunk gives rise to the auriculotemporal and inferior alveolar nerves, branches commonly associated with PNS, and the lingual nerve, which is seldom associated with PNS.

The auriculotemporal nerve, depicted in Figure 13-10, arises just below the foramen ovale and provides cutaneous innervation to a broad area of the lateral and upper face. It also provides postganglionic parasympathetic innervation to the parotid gland though the fibers that originate in the facial and glossopharyngeal nerves as the lesser superficial petrosal nerve.[27, 31] The lesser superficial petrosal nerve has a very complicated course, but ultimately it synapses in the otic ganglion just beneath the foramen ovale and then uses the auriculotemporal nerve as a conduit to reach the parotid gland.[31]

The inferior alveolar nerve enters the mandible via the mandibular foramen on the medial surface of the mandibular ramus and provides sensory innervation to the mandibular teeth and gingiva. It terminates as the mental nerve, which exits the mental foramen in the anterior mandibular body and provides cutaneous innervation to the lower lip and chin.

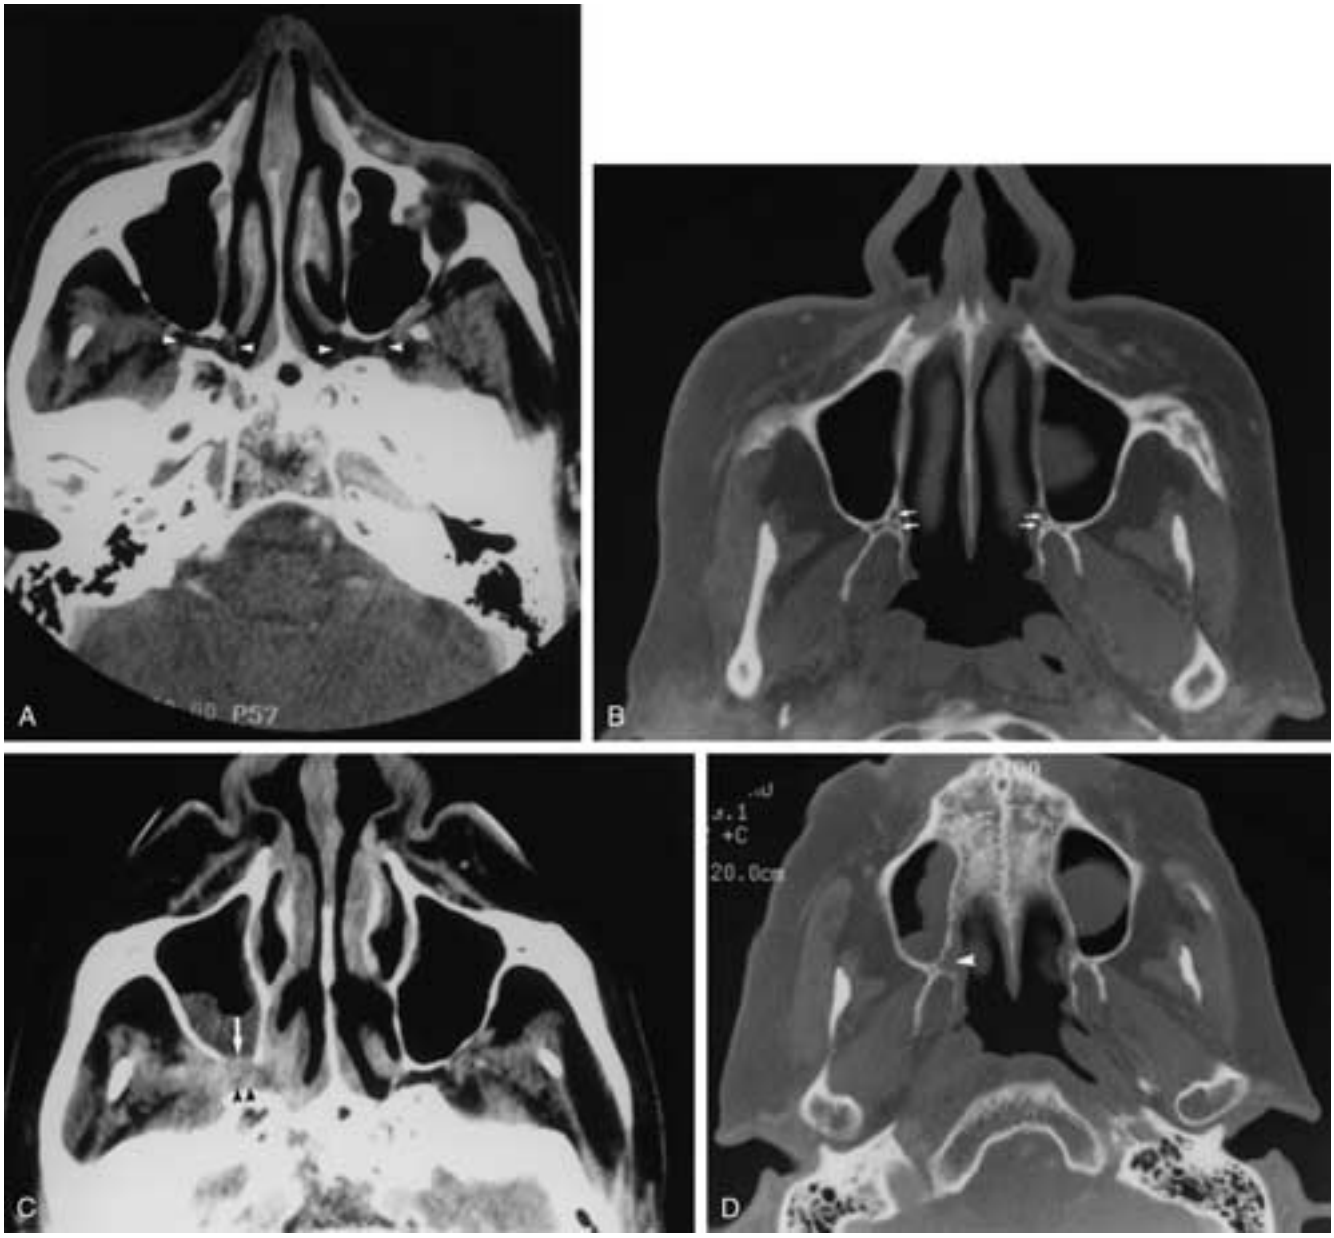
Tumors in any anatomic location supplied by V_3 can have retrograde PNS, ultimately involving the main trunk of the mandibular nerve within the masticator space. Tumor may then spread upward through the foramen ovale to eventually affect Meckel's cave.[13, 15, 18, 20] Thus, a skin cancer of the lower lip or chin can spread along the mental nerve to involve the inferior alveolar branch of V_3 and the main trunk of V_3, and ultimately extend through the foramen ovale (Figs. 13-11, 13-12).[11, 13] Parotid or lateral facial tumors can spread along the auriculotemporal branch of V_3 and thus gain access to the main trunk of the mandibular nerve (Fig. 13-13).[13, 15, 18] Any tumor originating within or spreading to the masticator space may have PNS along the mandibular nerve and extend through the foramen ovale (Figs. 13-14, 13-15). As mentioned, once tumor affects Meckel's cave, it can spread posteriorly along the main trigeminal trunk (Figs.

Copyright © 2003, Mosby, Inc. All rights reserved.

13-12, 13-15). Antegrade PNS may also occur from Meckel's cave to involve the cavernous sinus and subsequently V_2 (Fig. 13-12) or V_3 (Fig. 13-7D).

Facial Nerve

The anatomy of the facial nerve is complicated and need not be covered here in its entirety (see Chapters 19, 20, and 21). Diagrammatic representations of the facial nerve can be found in Figures 13-3, 13-17, and 13-20. Almost always, PNS involving the facial nerve occurs with malignancies that arise in the parotid origin or with nearby skin cancers that secondarily invade or metastasize to the parotid gland. These lesions may have PNS along the distal facial nerve (Fig. 13-16).[3, 13, 15] Tumor may then spread along the facial nerve to involve the posterior genu, horizontal or tympanic segment, geniculate ganglion, labyrinthine segment, or ultimately the intracanalicular portion within the internal auditory canal (Fig. 13-16). Less commonly, PNS may



VIEW IMAGE

FIGURE 13-6 Squamous cell carcinoma of the right soft palate with development of perineural spread along the palatine nerves. Axial contrast-enhanced soft-tissue (**A**) and bone window (**B**) CT scans at the time of diagnosis of the palate lesion. The PPFs (*arrowheads*) are normal. On the bone window images through the pterygoid plates, the palatine foramen are normal (*arrows*). The palatine branches of V_2 traverse these foramina en route to/from the palate and PPF. Axial contrast-enhanced soft-tissue (**C**) and bone window (**D**) CT scans at levels similar to those of **A** and **B** obtained 3 months later. There is abnormal widening and enhancement representing PNS within the right PPF (*arrowheads*). The posterior wall of the right maxillary sinus is destroyed (*arrow*). On the bone windows, the right palatine foramina are now destroyed (*arrowhead*). Compare with **B**. (From Ginsberg LE, DeMonte F. Imaging of perineural tumor spread from palatal carcinoma. FIGURE 13-8 Nasopharyngeal carcinoma with V_2 perineural spread. **A**, Axial T1-weighted MR image shows tumor in the right nasal cavity (*asterisk*) with lateral extension through a widened sphenopalatine foramen (*arrow*) involving the right PPF (*arrowheads*). To a lesser extent, the left PPF is similarly affected (*white dot*). Note that the central skull base is diffusely infiltrated by tumor (*brackets*). **B**, Axial contrast-enhanced, fat-suppressed T1-weighted MR image shows enhancement of all tumor components including the right PPF (*black dots*). Tumor is extending posteriorly along the right maxillary nerve through the foramen rotundum (*white arrowhead*) to involve the cavernous sinus (*asterisk*). The left cavernous sinus is also infiltrated by tumor, which could have arrived there along the internal carotid artery, a common route of spread in nasopharyngeal cancer. Note the subtle abnormal enhancement surrounding the cavernous segment of both internal carotid arteries (*black arrowheads*). Bilaterally, Meckel's caves remain intact, with CSF signal intensity and no enhancement centrally (*white dots*). (From Ginsberg LE. Imaging of perineural tumor spread in head and neck cancer. Semin Ultrasound CT MR 1999;2:175–186.)

involve the facial nerve from a small facial nerve branch, the greater superficial petrosal nerve.

Interconnections Between the Trigeminal and Other Cranial Nerves

As alluded to earlier, small distal branches of the trigeminal nerve serve as terminal conduits for branches of other cranial nerves, primarily the facial nerve. This relationship has implications for PNS, and many of these interconnections are depicted in Figure 13-17. The most important of these connections involves the greater superficial petrosal nerve (GSPN). This nerve is a branch of the facial nerve that provides parasympathetic innervation to the lacrimal gland, palate, nasal cavity, and nasopharynx.[27, 30] The anatomy of the GSPN is depicted in Figures 13-3, 13-17, and 13-18. Facial nerve fibers, originating in the nervus intermedius, leave the geniculate ganglion as the GSPN. Exiting from the superior surface of the temporal bone through a small foramen known as the facial hiatus (Fig. 13-19), the intracranial segment of the GSPN courses medially and anteroinferiorly along the surface of the petrous bone to the foramen lacerum. There it joins the deep petrosal nerve of the sympathetic carotid plexus to enter the vidian or pterygoid canal as the vidian nerve or nerve of the pterygoid canal (Fig. 13-3).[30] Upon exiting the vidian canal, this nerve enters the PPF, where the preganglionic fibers synapse in the sphenopalatine (pterygopalatine) ganglion. In the PPF, some of the postganglionic fibers join the palatine nerves (branches of V_2) and course inferiorly to the hard and soft palates (Fig. 13-17).[14] Other postganglionic parasympathetic fibers from the sphenopalatine ganglion supply secretomotor and vasomotor innervation to the nasal cavity and lacrimal gland via other branches of V_2 (Fig. 13-17).[30]

While it is theoretically possible that a lacrimal malignancy could spread via the fibers that connect it to the GSPN, this has not been reported. In practical terms, PNS along the GSPN usually occurs after any tumor reaches the PPF. Via PNS, the tumor gains access to the vidian nerve, and then spreads in a retrograde manner along the GSPN and into the geniculate ganglion (Fig. 13-9).[30] Also, as can be seen from Figure 13-18, the GSPN lies immediately beneath Meckel's cave, and as a result of this anatomic relationship, tumor within Meckel's cave may spread to the GSPN and then continue in a retrograde manner (Figs. 13-7, 13-12).[13] In Figure 13-12, a squamous cell carcinoma of the lower lip first spread along the mental and inferior alveolar branches of V_3, up through the foramen ovale into Meckel's cave, and then ultimately into the temporal bone and geniculate ganglion via the GSPN (Fig. 13-12).

Spinal Nerves

In the head and neck, PNS generally involves branches of cranial nerves. However, cutaneous innervation to much of the neck, as well as parts of the face, is provided by branches of the superficial cervical plexus, derived from the ventral divisions of the first four cervical spinal nerves (Fig.

13-20).[27, 32] A case of PNS along the great auricular nerve, a branch of this plexus, secondary to a recurrent skin carcinoma in the lower parotid region has been reported (Fig. 13-21).[32] It is possible that cutaneous malignancies in other locations may spread along other branches of the superficial cervical plexus, such as the lesser occipital or transverse cutaneous nerves, and even spread intraspinally.

IMAGING OF PERINEURAL TUMOR SPREAD

Little is known about the sensitivity and specificity of imaging of PNS, as there are few studies that directly address this issue. Nemzek et al. reported a detection rate of 95% but found that the mapping of the entire extent of PNS

VIEW IMAGE

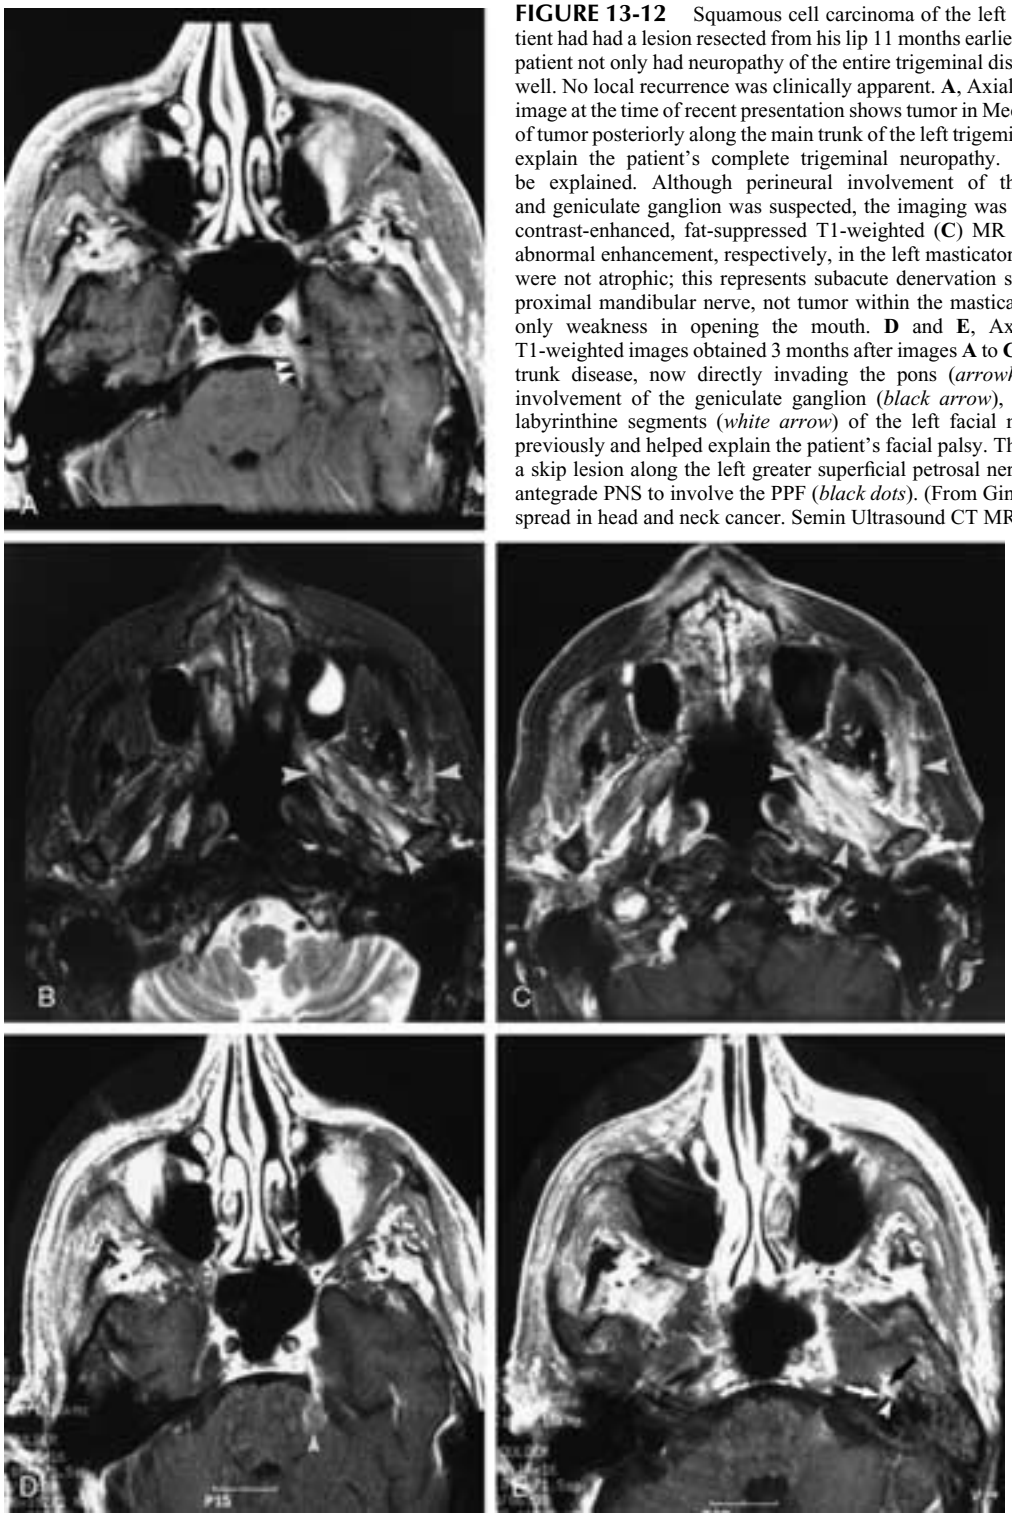

FIGURE 13-12 Squamous cell carcinoma of the left lower lip with extensive PNS. The patient had had a lesion resected from his lip 11 months earlier. At the time of recent presentation, the patient not only had neuropathy of the entire trigeminal distribution, but a facial nerve paralysis as well. No local recurrence was clinically apparent. **A**, Axial contrast-enhanced, fat-suppressed MR image at the time of recent presentation shows tumor in Meckel's cave (*black arrow*) and extension of tumor posteriorly along the main trunk of the left trigeminal nerve (*arrowheads*). These findings explain the patient's complete trigeminal neuropathy. However, the facial palsy could not be explained. Although perineural involvement of the greater superficial petrosal nerve and geniculate ganglion was suspected, the imaging was equivocal. Axial T2-weighted (**B**) and contrast-enhanced, fat-suppressed T1-weighted (**C**) MR images show hyperintense signal and abnormal enhancement, respectively, in the left masticator muscles (*arrowheads*). These muscles were not atrophic; this represents subacute denervation secondary to tumor involvement of the proximal mandibular nerve, not tumor within the masticator space. The patient had no trismus, only weakness in opening the mouth. **D** and **E**, Axial contrast-enhanced, fat-suppressed T1-weighted images obtained 3 months after images **A** to **C**. **D**, Progression of the main trigeminal trunk disease, now directly invading the pons (*arrowhead*), is seen. In **E**, there is tumor involvement of the geniculate ganglion (*black arrow*), proximal tympanic (*arrowhead*), and labyrinthine segments (*white arrow*) of the left facial nerve. This was not visible 3 months previously and helped explain the patient's facial palsy. This facial nerve disease was presumably a skip lesion along the left greater superficial petrosal nerve. In both **D** and **E**, there is probably antegrade PNS to involve the PPF (*black dots*). (From Ginsberg LE. Imaging of perineural tumor spread in head and neck cancer. Semin Ultrasound CT MR 1999;2:175–186.)

FIGURE 13-14 Nasopharyngeal carcinoma with lateral extension to the masticator space and mandibular nerve via PNS. Coronal contrast-enhanced, fat-suppressed T1-weighted image shows the left nasopharyngeal lesion (*large black dots*) with lateral extension to involve the upper masticator space (*asterisk*). Tumor is extending perineurally through the widened foramen ovale (*small black dot*). Although there is tumor in the most proximal aspect of the mandibular nerve (*arrowhead*), Meckel's cave (*white dot*) appears to be spared. (From Ginsberg LE. Imaging of perineural tumor spread in head and neck cancer. Semin Ultrasound CT MR 1999;2:175–186.)

was only 65% accurate.[21] The latter number might have been higher if fat suppression had been employed on the postcontrast sequences used in that study. For the imaging of PNS, sensitivity and specificity are difficult to measure with certainty because, in many cases, the imaging is so suggestive of PNS that biopsy is not performed.

Another factor limiting the imaging sensitivity and specificity for PNS is the imaging technique. Even in the presence of definite PNS, inadequate technique (or artifact, patient motion, etc.) can result in the disease being inconspicuous on the images and therefore not diagnosed. If proper imaging technique is adhered to, the overwhelming majority of PNS can be detected prior to initiating therapy.

Technical Considerations

One of the most important technical considerations is a knowledge of the indications for the imaging study prior to the examination. This allows the study to be tailored to the specific problem. Often, a CT or MR examination has been performed as a routine brain study with a 23 cm field of view (FOV). In this setting, detection of PNS is compromised, as the FOV is excessive and the images are too small to reveal fine neural structures. Whether the examination is a CT or an MR imaging study, the FOV should be no greater than 18 cm and preferably only 16 cm. Thin slices, 3 to 5 mm, should be obtained. For CT, high-resolution bone algorithm

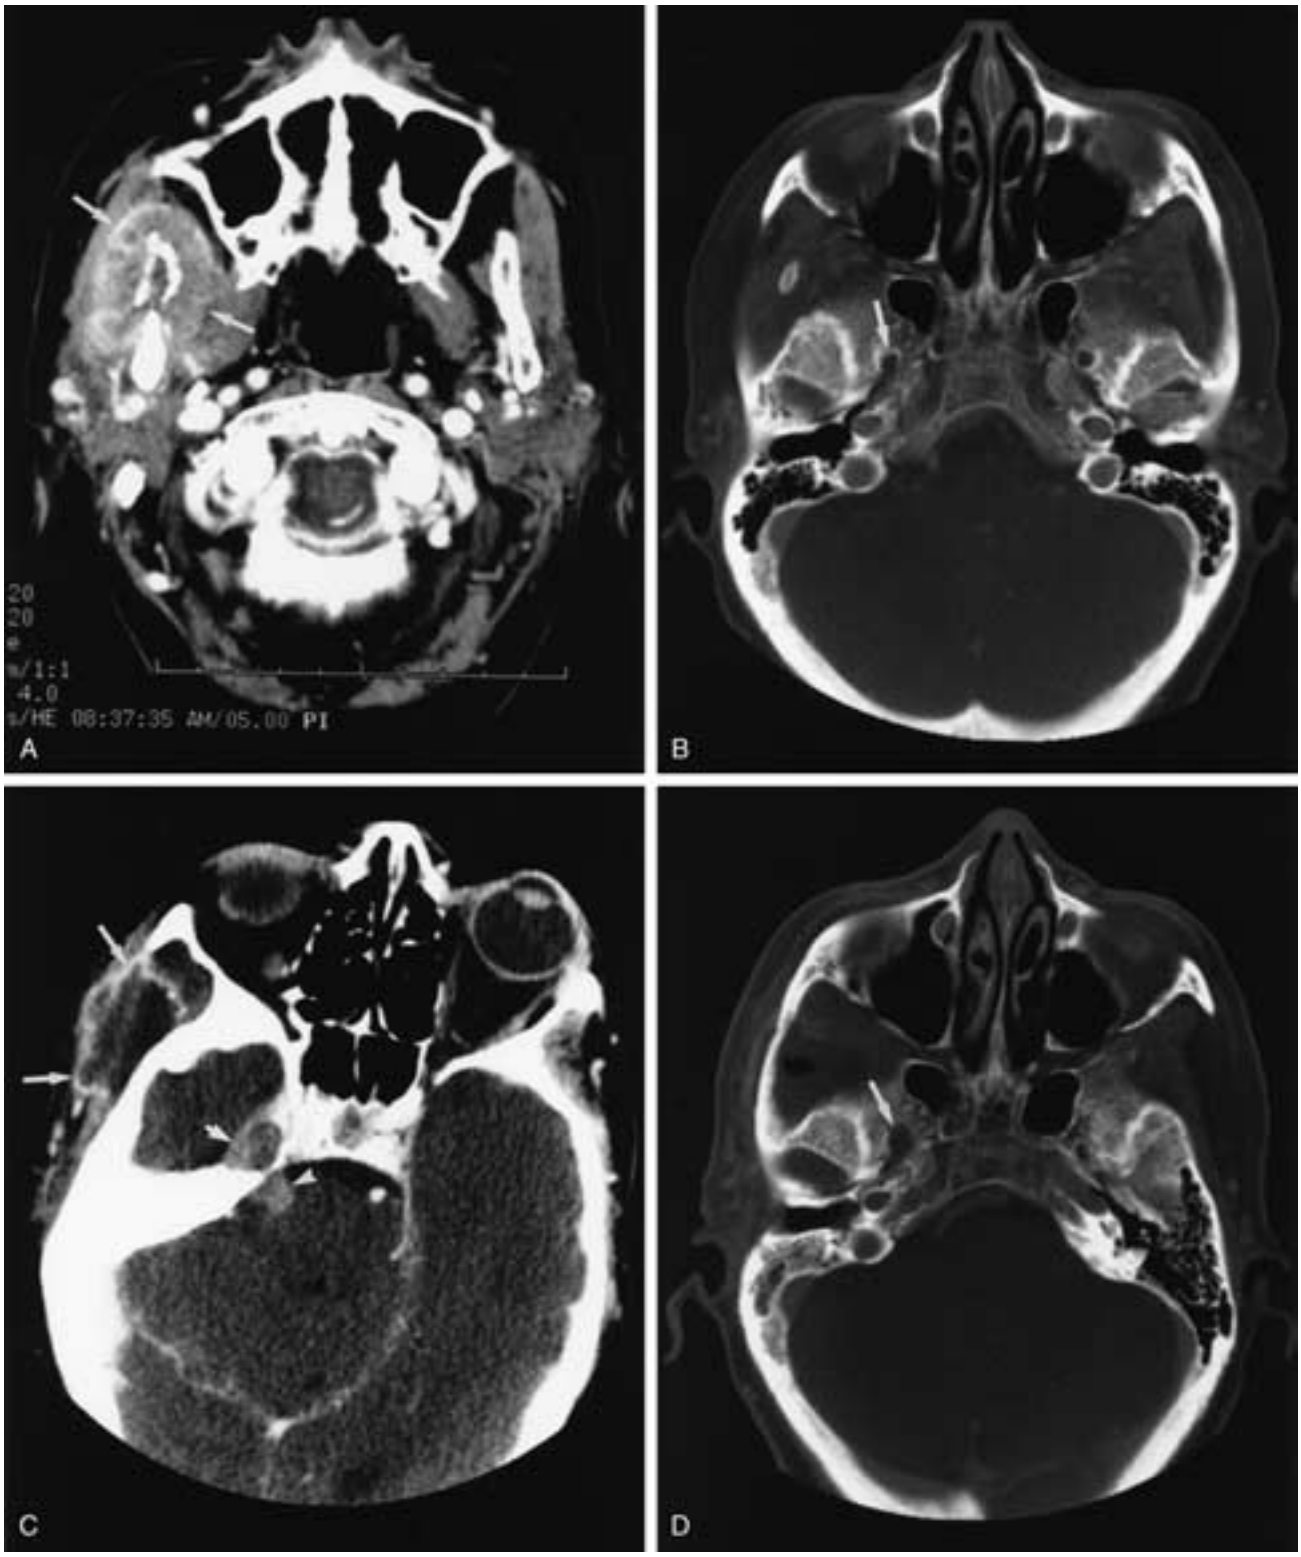

FIGURE 13-15 Squamous cell carcinoma of the right retromolar trigone with extension into the masticator space and subsequent PNS along V_3. Axial contrast-enhanced CT soft-tissue (**A**) and bone window (**B**) images at presentation show extensive tumor involvement of the right mandibular ramus and adjacent musculature (*arrows* in **A**). Note that the foramen ovale is normal, with intact cortical margins (*arrow* in **B**). No intracranial abnormality was visible on higher images at this time. Axial contrast-enhanced CT soft-tissue window (**C**) and bone window (**D**) images obtained 6 months after **A** and **B**. Despite surgery and radiotherapy, the patient had a large recurrence (*long arrows* in **C**). Note the enlargement and loss of the cortical margin in the right foramen ovale, suggesting PNS (*arrow* in **D**; compare this with the appearance of the foramen ovale in **B**). The soft-tissue window image shows enlargement and central enhancement indicating tumor in Meckel's cave (*short arrow* in **C**) with continued spread to involve the main right trigeminal trunk (*arrowhead*).

FIGURE 13-16 Adenocarcinoma of the left parotid gland with PNS along the facial nerve. **A**, Axial contrast-enhanced SPGR MR image obtained at an outside facility 1 month after left parotidectomy. The facial nerve was paralyzed postoperatively. This study was read as postoperative changes only; no mention was made of the abnormal enhancement and enlargement of the left descending facial nerve segment (*arrowhead*). The right descending facial nerve is normal (*arrow*). The tympanic and more anterior aspects of the left facial nerve are normal. Postoperatively, the patient had radiotherapy to the parotid region. **B**, Axial contrast-enhanced SPGR MR image obtained at an outside facility 20 months after **A**, by which time the patient had developed left-sided hearing loss. There is tumor in the geniculate ganglion (*black dot*), proximal greater superficial petrosal nerve (*arrow*), and internal auditory canal (*arrowhead*). This case demonstrates progression of PNS with initial failure to diagnose. The patient ultimately developed widespread leptomeningeal disease.

images should also be generated for evaluation of subtle bone erosion.

When MR imaging is performed, it is crucial to obtain axial T1-weighted images prior to the administration of contrast. This is necessary because the normal hyperintense signal intensity of fat in the PPF and foraminal areas is best assessed on this sequence. The presence of PNS has been overlooked, in part, because this sequence was omitted (Fig. 13-4). Although there is some controversy in the literature as to whether postcontrast MR imaging should be fat suppressed, it is generally agreed that in the evaluation of PNS, fat suppression should be used.[32] Though this technique is sometimes prone to artifact, there are numerous cases in which the lack of fat suppression has made PNS either difficult to see or completely inconspicuous (Figs. 13-4, 13-11). Postcontrast axial and coronal MR images should be obtained routinely.

Imaging Diagnosis of PNS

On CT, imaging findings suggestive of PNS include widening or destruction of neural foramina/canals, excessive enhancement within neural foramina/canals, or excessive enhancement or widening of the cavernous sinus, PPF, or Meckel's cave. In addition, the loss of fat planes immediately adjacent to neural foramina or within the PPF, even in the absence of abnormal enhancement, widening, or bone destruction, are highly suggestive findings of PNS (Figs. 13-6, 13-15).[13, 18, 28, 34–36] Caution should be used when interpreting bone destruction on CT, as it may simply be the direct effect of the tumor rather than PNS (Fig. 13-22).

VIEW IMAGE

On MR imaging, findings suggestive of PNS include any of the following: excessive enhancement of a cranial nerve branch (either within the cisternal portion or within a canal or foramen), loss of the normal fat pad adjacent to a foramen,[34, 35] or widening/excessive enhancement within the PPF, Meckel's cave, or the cavernous sinus (Figs. 13-2, 13-4, 13-5, 13-7 to 13-9, 13-11, 13-14, 13-16, 13-23). Again, loss of the normal T1-hyperintense fat in the PPF should be regarded as highly suspicious for PNS (Figs. 13-5, 13-8).

With regard to Meckel's cave, the site of the gasserian (trigeminal) ganglion, this space is filled primarily with CSF. As such, it should be of fluid density on CT and of fluid signal intensity on MR imaging. The ganglion has only some peripheral vascularity, and as such, there normally should be no central enhancement within Meckel's cave. Such enhancement is a strong indicator of the presence of disease (Figs. 13-7, 13-9, 13-12, 13-13, 13-15, 13-23).[13] In severe cases of PNS affecting the trigeminal nerve, it may be possible to observe thickening and abnormal enhancement of the main trigeminal trunk extending back from Meckel's cave toward the brainstem (Figs. 13-12, 13-13, 13-23). Although MR imaging is better at detecting PNS in the main trigeminal trunk, it can sometimes be seen with CT (Fig. 13-15).

VIEW IMAGE

FIGURE 13-22 Squamous cell carcinoma of the right parotid gland with CT bone findings suggesting PNS along the descending facial nerve and stylomastoid foramen. The coronal CT bone window shows bone destruction at the stylomastoid foramen (*arrow*). The facial nerve canal was explored at surgery, and the nerve was found to be normal. These bone changes, though consistent with PNS, were secondary to the direct effects of the primary tumor.

VIEW IMAGE

FIGURE 13-23 Squamous cell carcinoma of the right forehead with very subtle PNS along the ophthalmic nerve (V_1). One year after excision of the primary skin cancer, the patient developed sensory neuropathy in the entire right trigeminal distribution. Axial (**A**) and coronal (**B**) contrast-enhanced, fat-suppressed T1-weighted MR images show very subtle abnormal enhancement within Meckel's cave on the right (*arrows* in **A** and **B**) and even subtler enhancement of the main trigeminal trunk (*arrowhead* in **A**). Biopsy of the right supraorbital region confirmed perineural infiltration of the supraorbital branch of V_1. The abnormal enhancement was presumed to represent a skip lesion originating on V_1, as there was no imaging evidence of tumor in the orbit, superior orbital fissure, or cavernous sinus. The patient received radiotherapy, as the disease was deemed inoperable. **C**, Axial contrast-enhanced, fat-suppressed T1-weighted MR image obtained 8 months after **A** and **B** shows massive disease recurrence/progression with bulky tumor in Meckel's cave (*asterisk*) and the pons (*black dot*).

Copyright © 2003, Mosby, Inc. All rights reserved.

The radiologist should also be alert to the potential for *skip lesions*, segments of normal intervening nerve between regions of PNS (Figs. 13-12, 13-23).[7, 10, 33, 37] In the literature, skip lesions have also been referred to as *resurfacing*. As previously mentioned, the radiologist should also be aware of the presence of antegrade PNS (Fig. 13-7).

Secondary Imaging Findings

The presence of secondary findings associated with PNS may either lend support to a case of suspected PNS or alert the radiologist to the presence of undiagnosed PNS. These findings chiefly are those of denervation of the mandibular division of the trigeminal nerve, whose branches innervate the muscles of mastication as well as the anterior belly of the digastric and mylohyoid muscles.[18, 38] In the chronic stages (more than 20 months following denervation), these muscles undergo fatty infiltration and/or atrophy, findings readily seen on CT or MR imaging (Fig. 13-24).[18, 38]

However, in the acute (less than 1 month) and subacute (1 to 20 months) stages of muscular denervation, there are findings that are seen only on MR imaging. These findings include increased T2-weighted signal intensity and abnormal enhancement within the affected muscles (Fig. 13-12).[38, 39] Although these imaging findings may suggest tumor involvement, particularly if the primary tumor is nearby, there are ways to differentiate tumor from denervation. On imaging, subacutely denervated muscle retains its internal striations, which are generally lost in the presence of tumor.[40] Clinically, a patient with tumor in the masticator muscles usually has trismus, whereas a patient with denervation has weakness of the masticator musculature.

VIEW IMAGE

FIGURE 13-24 Oral cavity squamous cell carcinoma with spread to the masticator space, V_3 PNS, and chronic denervation of the V_3-innervated musculature. Coronal contrast-enhanced CT scan shows tumor in the left pterygoid musculature (*large black dots*) and within the foramen ovale (*small black dot*). Note the atrophy of the mylohyoid (*arrowheads*), anterior belly of the digastric (*asterisk*), and masseter muscles (*arrows*) on the left side.

IMAGING PITFALLS

Various pitfalls exist in the imaging of PNS. Alone or in concert, they may result in PNS either not being diagnosed or being overdiagnosed.

Technique

As previously mentioned, if proper imaging technique is not employed, it is easy to overlook the diagnosis of PNS. The use of an excessively large FOV, the lack of a T1-weighted axial MR image to evaluate the PPF, and the lack of fat suppression on postcontrast MR imaging (Figs. 13-4, 13-11) are all problems that may contribute to the missed diagnosis of PNS.

Questionable PNS

In the early stages of PNS, the imaging findings can be extremely subtle. In some cases the findings are subtle but definite (Fig. 13-23), while in other cases the findings are so subtle as to be questionable. In the latter case, the radiologist must inform the surgeon of the possibility of PNS so that either a surgical exploration is performed to prove or disprove the presence of PNS or early follow-up imaging is obtained to evaluate the possible progression of PNS.

Asymmetric Foraminal Enhancement

All of the neural foramina and canals of the skull base normally contain emissary veins.[31] Slow-flowing blood within these veins usually results in some degree of enhancement after contrast administration, particularly on fat-suppressed MR images (Figs. 13-13B, 13-25).[41] Although most of the skull base foramina are quite symmetric, some normal asymmetry can occur.[31] If the patient is scanned with a slightly tilted or rotated scan angle, any asymmetry of these foramina should be viewed with caution prior to diagnosing an abnormality. That is, the radiologist should be certain that any asymmetry in the size of these foramina or in the degree of enhancement is truly caused by disease and not by asymmetric scanning of the patient.

PERSISTENT POSTTREATMENT IMAGING ABNORMALITIES

Following treatment for proven or strongly suspected PNS, the imaging findings may remain abnormal for an indefinite period of time. The imaging findings may rival the original appearance of PNS despite the lack of clinical evidence of persistent or progressive disease.[42] Obviously, on a given imaging study, it is impossible to exclude active

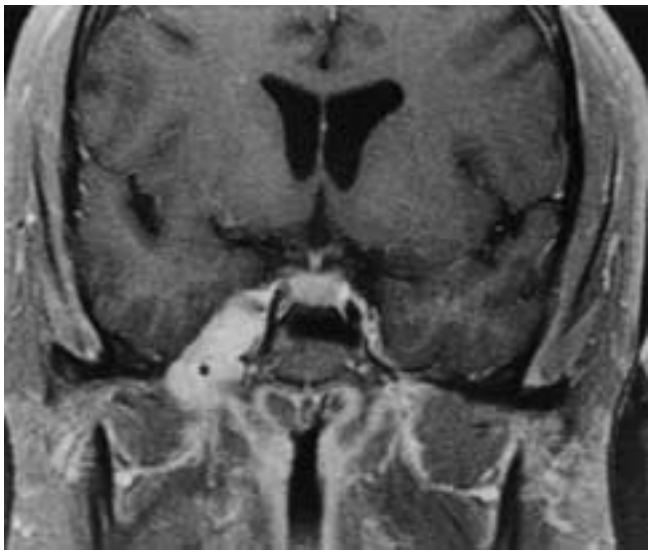
FIGURE 13-25 Normal foraminal enhancement on MR imaging. Axial contrast-enhanced, fat-suppressed T1-weighted MR image shows normal enhancement of both vidian canals (*small arrowheads*), both foramina ovale (*arrows*), and the left foramen spinosum (*large arrowhead*).



VIEW IMAGE

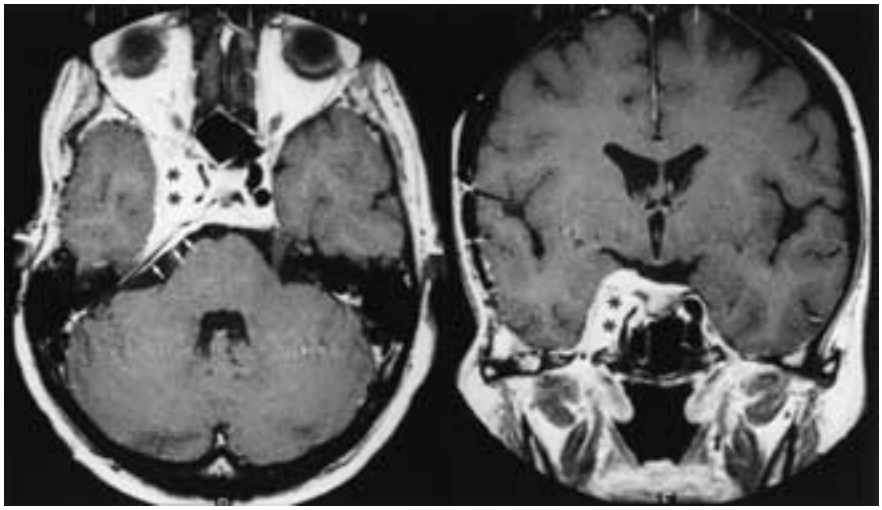
FIGURE 13-27 Right cavernous sinus/Meckel's cave schwannoma with extension through the foramen ovale. Coronal contrast-enhanced, fat-suppressed T1-weighted MR image shows an enhancing mass extending inferiorly through a grossly widened foramen ovale (*asterisk*). For Figures 13-26 and 13-27, prior to establishing the diagnosis, the possibility of PNS from a head and neck cancer should at least be considered and sought radiographically. (From Ginsberg LE. Imaging of perineural tumor spread in head and neck cancer. Semin Ultrasound CT MR 1999;2:175–186.)

disease in the face of findings that suggest PNS. However, one should be aware that imaging findings of PNS may not revert to normal even if the disease has been successfully treated.

It has been shown that once the PPF is violated surgically, images of this structure will appear abnormal indefinitely.[43] The persistent imaging findings consist of loss of the normal high T1-weighted fat signal intensity and the presence of excessive enhancement on contrast-enhanced images. Unfortunately, these findings are identical to those seen with PNS. Therefore, following surgery of the PPF, imaging studies should be interpreted with caution to avoid overdiagnosing PNS or local recurrence.[43] The best way to evaluate PPF is to compare serial follow-up imaging studies.

MIMICS OF PNS

The radiologist should be aware that there are other diseases that may have imaging and clinical findings identical to those of PNS. While there may be adjunctive clinical or radiologic signs that point to such a diagnosis, any given case may nonetheless present a diagnostic challenge. Thus, meningioma, occurring near a neural foramen, may extend through that foramen and mimic PNS (Fig. 13-26).[13]



VIEW IMAGE

FIGURE 13-26 Cavernous sinus/Meckel's cave meningioma with extension through the foramen ovale. Left (axial) and right (coronal) contrast-enhanced T1-weighted MR images without fat suppression show a characteristic right cavernous sinus/Meckel's cave meningioma (*asterisks*). Note the dural tail extending posteriorly along the right petrous ridge (*arrows*). The lesion is seen on the coronal image to be extending inferiorly through a widened foramen ovale (*black dot*). (From Ginsberg LE. Imaging of perineural tumor spread in head and neck cancer. Semin Ultrasound CT MR 1999;2:175–186.)

Copyright © 2003, Mosby, Inc. All rights reserved.

Occasionally a schwannoma, particularly when it involves the trigeminal or facial nerves, may mimic PNS (Fig. 13-27). Finally, though uncommon and probably clinically obvious, advanced rhinocerebral mucormycosis may spread along cranial nerve branches and appear quite similar on imaging to PNS.[44]

CONCLUSION

It is clear that PNS is a serious complication and a major diagnostic challenge. Only by learning more about the relevant neuroanatomy and by obtaining a thorough clinical history of the head and neck cancer patient can the radiologist properly perform and interpret imaging studies so as to ensure that PNS is accurately diagnosed.

EMBRYOLOGY OF THE JAWS

Embryologically, the maxilla, mandible, and facial soft tissues arise from a number of structures early in the fourth week of development. These structures are the central unpaired frontonasal prominence, the paired nasomedial processes, and the paired maxillary and mandibular prominences. The last three of these arise from the first branchial arch. These all surround a ventral depression, the stomodeum, which will later become the mouth. These structures arise from neural crest tissues (Fig. 14-1) and are also described in detail in Chapter 1.[1–4]

As the embryo develops, the nasomedial and maxillary processes become more prominent and fuse to form the upper lip and upper jaw. The two nasomedial processes fuse to form the intermaxillary segment that is the precursor for the philtrum of the upper lip, the primary palate, and the premaxillary component of the upper jaw. These structures merge by intermingling of the underlying mesenchyme and disintegration of the overlying epithelia. The frontonasal prominence is displaced as the nasomedial processes merge, and it does not contribute significantly to the upper jaw.[1,4]

The mandible forms from the enlargement and fusion of the bilateral mandibular prominences. The mandibular skeleton develops from a cartilaginous derivative of the first branchial arch called *Meckel's cartilage.* When the maxillary and mandibular processes fuse laterally, they form the corners of the lips, or commissures.

As these facial structures are formed, mesenchymal cells of the first and second branchial arches invade them and form the muscles of mastication (first branchial arch, supplied by cranial nerve V, the trigeminal nerve) and the muscles of facial expression (second branchial arch, supplied by cranial nerve VII, the facial nerve).

Most of the differential jaw and facial growth occurs between 4 and 8 weeks, but changes occur in the different regions at different rates throughout fetal development and the early neonatal period. Relative to the adult, the neonatal face is small due to the fact that the jaws are still rudimentary at birth, the teeth undeveloped and unerupted, and the paranasal sinuses small.

As mentioned above, the various components forming the jaws fuse and mesenchymal merging occurs, leaving only the two nostrils and mouth as normal openings. If there is any interference with this process, a number of anomalies can occur, resulting in cleft lip, cleft chin, cleft anterior palate, and clefts at the corners of the mouth. If the

Copyright © 2003, Mosby, Inc. All rights reserved.

commissures do not form correctly, a large mouth or macrostomia can occur (also see Chapter 1).

EMBRYOLOGY OF THE DENTITION

The process by which the teeth form is called odontogenesis. Humans have two sets of teeth: the primary dentition (deciduous) and the secondary dentition (permanent). The presence of teeth in the maxilla and mandible contributes to the formation of the jaws and to the final shape of the face. There are 20 deciduous teeth and 32 permanent teeth.

Each tooth develops from ectoderm and ectomesenchyme (mesenchyme of the head). The enamel arises from the ectoderm, while the other tissues (dentin, cementum, periodontal ligament, and pulp contents) arise from the mesenchyme. The mesenchyme (ectomesenchyme) represents a migration of neural crest cells into the developing arches of the mandible and maxilla. Tooth development begins with the formation of the primary dental lamina invaginating into that mesenchyme. This dental lamina is a thickening of the oral epithelium overlying the jaws. These cells migrate into the primitive jaws in the sixth week of development. In 10 places in each of the mandibular and maxillary arches, cells of this dental lamina start to multiply faster than the surrounding cells and condense to form the tooth buds or tooth germs.[1–4]

Each tooth will develop and erupt at a specific time, but the overall pattern of odontogenesis is common to all teeth. The tooth germs of the permanent succedaneous teeth (the permanent teeth replacing deciduous teeth) arise from the secondary dental lamina and appear lingual to each deciduous tooth germ. These permanent succedaneous teeth are the permanent central and lateral incisors, canines, and first and second premolars. The premolars arise from the secondary lamina associated with deciduous (primary) molars and erupt into their corresponding positions. The permanent first, second, and third molars arise from the primary dental lamina posterior to the primary second molar. All the tooth buds except for the second and third permanent molars are present and start developing before birth.

As the tooth bud grows, it develops into a cap shape by invagination of mesenchyme (Fig. 14-2). The ectodermal component forms the enamel organ, which is composed of the outer enamel epithelium, the stellate reticulum, and the

VIEW IMAGE

inner enamel epithelium. A layer of more condensed cells develops from the stellate reticulum along the inner enamel epithelium, called the stratum intermedium. The enamel forms from the inner enamel epithelium, whose cells elongate into ameloblasts. Ameloblasts form the enamel of the tooth (Fig. 14-3).[2,3]

The invaginating mesenchyme forms the dental papilla. The peripheral cells of the dental papilla take on a columnar form and become known as *odontoblasts.* These cells will form the dentin of the tooth. The ameloblast and odontoblast layers are separated by a basement membrane. The future dentinoenamel junction is demarcated by the basement membrane. The dental papilla will later form the dental pulp, which is the soft tissue inside the root chamber of the tooth and contains nerves, vessels, and connective tissue.

At this stage, the tooth bud is starting to take on the shape of a bell and is called the *bell stage.* Later in the bell stage, the ameloblasts and odontoblasts start to produce the precursors of enamel and dentin. This starts to occur at about the fifth fetal month. The enamel is formed in a matrix in the shape of rods or a prism, but only after predentin is formed next to the inner enamel epithelium. In other words, enamel formation (amelogenesis) is induced by the production of dentin (dentinogenesis) (Fig. 14-4). Predentin later calcifies into dentin as the tooth develops. Both amelogenesis and dentinogenesis begin at the cusp or top of the tooth, and these processes continue toward the future apex or root. Enamel formation occurs only in the preeruptive tooth, while dentin deposition occurs throughout life. Enamel formation terminates with the development of an organic layer, the enamel cuticle. After this forms, the inner and outer enamel epithelia and the remains of the stratum intermedium form the reduced enamel epithelium, which fuses with the overlying oral epithelium to induce eruption of the teeth (movement of the tooth into the oral cavity).[2,3]

The dental laminae (primary and secondary) start to disintegrate at this stage. The cells of the dental lamina can disappear completely or can remain as groups of epithelial cells. These remnants may later give rise to lesions such as odontogenic (of tooth origin) cysts. As this occurs, further condensation of the mesenchyme around the tooth bud occurs, forming the dental sac. Also, the tooth buds become surrounded by islands of bone matrix that are developing in the jaws. Cells of the dental sac will produce other components of the teeth, such as cementum and the periodontal ligament. These will anchor the tooth in the bony socket (alveolus) of the jaws. As the teeth form, they start to migrate toward the surface of the jaws. Usually, no

teeth are seen in the mouth at birth, but natal teeth can occasionally be seen. Teeth erupt at different times during life in a fairly predictable pattern (Table 14-1).[3]

A number of anomalies of tooth development can occur.[5] These anomalies include too many teeth (supernumerary), too few teeth (hypodontia), the total lack of teeth (anodontia), or abnormal tooth shape and size, which may involve either the crown or the roots. Included are conditions such as fused teeth, enlarged teeth (macrodontia), or small teeth (microdontia); development of dentin and enamel can be faulty, resulting in conditions such as amelogenesis and dentinogenesis imperfecta. In these cases, the teeth are soft and prone to caries (dental decay), as well as to fracture from minor trauma, and anomalies of eruption, which include ectopia (tooth found in an abnormal position), impaction (impedance of eruption by bone or another tooth), ankylosis (the tooth is attached directly to bone, with no periodontal ligament), and delayed and premature eruption.

ANATOMY

Dentition and General Considerations

The teeth of the mandible and maxilla are each embedded in a horseshoe-shaped bony ridge called the alveolar process. Each process divides the oral cavity into two compartments: a more central one adjacent to the tongue called the oral cavity proper and a more peripheral one adjacent to the cheeks and lips called the oral vestibule. A horseshoe-shaped furrow formed where the mucous membrane of the lip and cheek reflect up onto the alveolar process is termed the fornix vestibuli. In the midline, vertically oriented folds of mucosa, the labial frenula, help connect the upper and lower lips to the alveolar process. The lingual frenum, or frenulum, is a similar structure in the midline on the undersurface of the tongue.

When fully dentured, the adult jaw contains 32 teeth—16

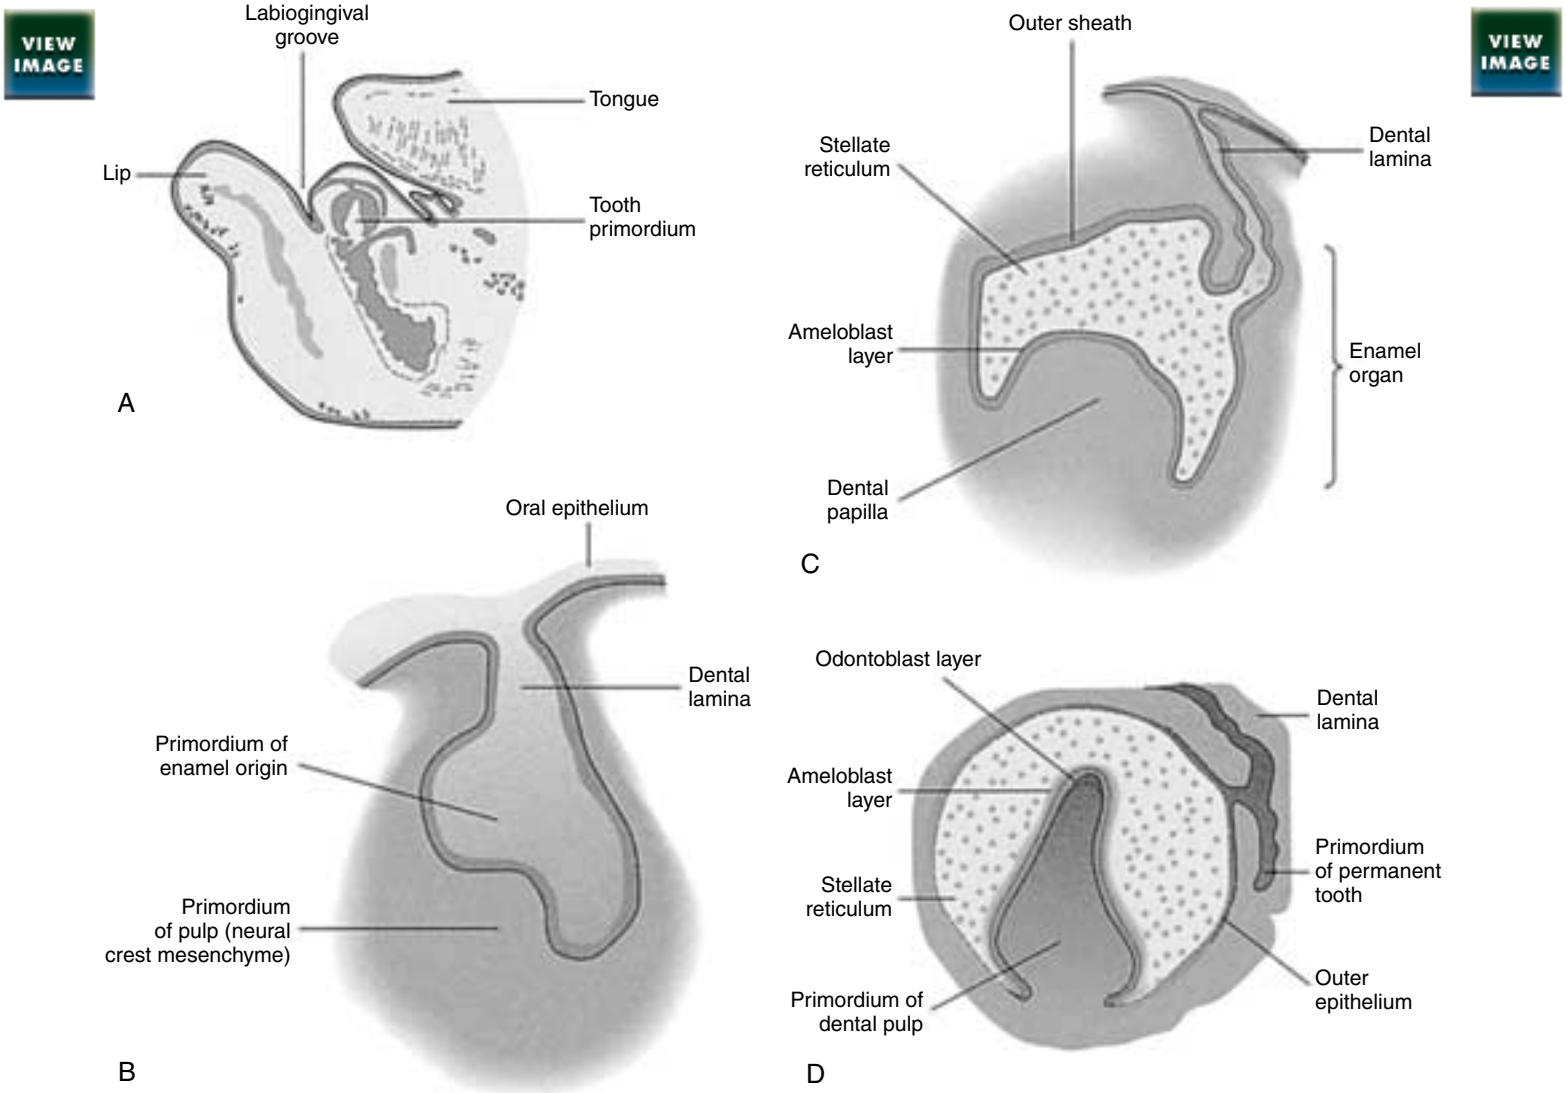

FIGURE 14-2 The development of a deciduous tooth. **A**, Parasagittal section through the lower jaw of a 14-week-old human embryo showing the relative location of the tooth primordium. **B**, Tooth primordium in a 9-week-old embryo. **C**, Tooth primordium at the cap stage in an 11-week-old embryo, showing the enamel organ. **D**, Central incisor primordium at the bell stage in a 14-week-old embryo before deposition of enamel or dentin.

in the maxilla and 16 in the mandible. The teeth can be referred to by number or by name (Fig. 14-5). They are numbered sequentially, starting in the posterior right maxilla with tooth number 1 and continuing to number 16 in the posterior left maxilla. In the mandible they continue with tooth number 17 in the posterior left and end with tooth number 32 in the posterior right. The teeth are named beginning in the midline and moving distally on either side as follows: the central incisor, the lateral incisor, the canine, the first premolar, the second premolar, the first molar, the second molar, and the third molar.

The dentition of the pediatric jaw is different than that of the adult jaw. When fully dentured, it contains 20 teeth, 10 in the maxilla and 10 in the mandible, instead of the 32 teeth in the adult. Children lack the premolars and third molars. Instead of numbers, the teeth can be referred to by letter or by name (Fig. 14-5). They are lettered sequentially starting in the posterior right maxilla with tooth letter A (maxillary

FIGURE 14-4 Illustration of an advanced tooth germ with enamel (*E*) and dentin (*D*) present in the coronalmost part. Ameloblasts are present around the enamel, whereas cervically the inner epithelial cells have not yet differentiated into ameloblasts. The dental sac surrounds the enamel organ and is continuous with the dental papilla. Developing bone (*B*) of the jaw is present, and the developing tooth is separated from the oral epithelium (*OE*) by connective tissue (*CT*). (From Melfi RC. Permar's Oral Embryology and Microscopic Anatomy. Philadelphia: Lea & Febiger, 1994.)

The portion of the tooth exposed in the oral cavity is called the anatomic crown (arrowheads in Fig. 14-6C), and the portion of the tooth embedded in the bony socket is referred to as the root (Fig. 14-7B). Most of the tooth is composed of dentine; however, the outer surface of the crown is covered by the smooth, dense enamel, and the outer surface of the root is covered by dense cementum, a tissue very similar to bone. A constriction where the crown and root meet is referred to as either the cervical constriction or the cementoenamel junction (Cc in Fig. 14-7B).

On CT, particularly in young people, the dense enamel appears separate from the dentine and looks like a dense band covering the crown of the tooth (E in Fig. 14-7B). With age, receding gingiva and bone cause portions of the root to be exposed in the oral cavity. The crown now differs from the original anatomic crown (that portion covered with enamel) and should be referred to as the functional crown. The arrows in Figure 14-6C point to the functional crown, and the arrowheads point to the anatomic crown.

The neurovascular bundle of the tooth enters the root apex via the apical foramen and travels through the root canal and into an expanded pulp chamber in the crown. The root canal and pulp chamber are seen on CT as a relatively radiolucent area in the center of the root and crown (Fig. 14-7B). Accessory apical foramina along the side of the root, rather than the apex of the root, may occasionally exist.

Each crown has five free surfaces.[6] The biting surface, or the surface where the upper and lower teeth oppose each other, is referred to as the occlusal surface (Figs. 14-6A and 14-7B). The surface facing toward the inside, or toward the oral cavity, is called the lingual surface in the mandible and the palatal surface in the maxilla (Fig. 14-6A). The outer surface of the tooth facing toward the lip and cheek is termed the labial surface for the incisors and canines and the buccal surface for the premolars and molars (Fig. 14-6C). This surface may more simply be referred to as the facial surface for all the teeth. The other tooth surfaces are the contact surfaces where one tooth contacts a neighboring tooth. Of

FIGURE 14-5 Illustration showing letter nomenclature of pediatric teeth (*A*) and number nomenclature of adult teeth (*B*).

these two surfaces, the one closest to the midline is referred to as the mesial surface, and the other is referred to as the distal surface (Figs. 14-6C and 14-7B). The mesial surface in the incisors and canines may also be called the medial surface, but in the premolars and molars it is termed the anterior surface. Likewise the distal surface in the incisors and canines may be called the lateral surface and in the premolars and molars the posterior surface.

Direction also can be described with this terminology. For example, toward the midline would be referred to as mesial, or anterior, and moving in the direction of the molars would be referred to as distal, or posterior. When referring to the crown of the tooth, one may move in the occlusal direction (toward the opposing tooth) or in the cervical direction (toward the cervical constriction), and when referring to the root, one may move in the cervical or apical direction. The use of this terminology is nicely exemplified by naming the roots of the teeth. For example, the first mandibular molar contains three roots, two buccal and one lingual. Of the two buccal roots, one is termed the mesiobuccal and the other is termed the distobuccal (Fig. 14-7B). The lingual one is simply called the lingual root.

The teeth are held in the bony socket by a highly specialized periodontal ligament that provides the teeth with small degrees of motion or ''give'' within the socket. On plain films, the ligament appears as a radiolucency between the cementum of the root and the lamina dura of the bony socket. The periodontal space normally measures between 0.1 and 0.2 mm and is therefore not typically identified on CT. Figure 14-7A, however, does show the lamina dura and to a lesser degree the periodontal space. A radiolucency seen on CT between the tooth root and the alveolar bone may represent a pathologic state such as periodontal disease, which is discussed later. In the cervical portion of the tooth, the fibers of the periodontal ligament radiate from the cementum of the root into the gingiva and serve to attach the gingiva to the tooth.

MANDIBLE

The anatomy of the mandible is described on the anatomic specimen in Figure 14-6 and on the illustrations of the neurovascular and muscular structures in Figures 14-8 and 14-9.[6–15] This anatomy is then labeled on the cross-sectional, axial, and panoramic CT images in Figure 14-10.[16]

Anatomic Specimen

Lingual Surface

The mandibular nerve, the third division of the trigeminal nerve, and the mandibular artery (Fig. 14-8A), enter the lingual surface of the mandible through the mandibular foramen (Mf in Fig. 14-6A). The foramen is situated in the center of the ramus, 1 to 2 cm posterior to the third molar at the craniocaudal level of the crowns of the teeth. The nerve and artery then travel anteriorly in the inferior alveolar canal (mandibular canal) (Fig. 14-8A). The canal typically hugs the lingual aspect of the mandible until it curves labially to exit the mandible at the mental foramen (M in Fig. 14-6C; Fig. 14-8A), which on the labial surface of the mandible is between the first and second premolars at the level of the roots. As the neurovascular bundle travels through the mandible, small nutrient canals extend coronally to supply the teeth (Fig. 14-8A, *arrow*). At the mental foramen the main trunk of the mandibular nerve exits as the mental nerve and supplies sensory fibers to the skin overlying the mandible and lower lip (Fig. 14-8A). A smaller branch, the incisive nerve, continues toward the midline within the mandible in the incisive canal (Fig. 14-11). It is accompanied by the incisive artery. This nerve innervates the canine and lateral incisor teeth, and the artery exits through the lingual foramen, which is located in the midline, inferiorly on the lingual aspect of the mandible (Lf in Figs. 14-6B and 14-11C). After exiting the mandible, this

Copyright © 2003, Mosby, Inc. All rights reserved.

artery anastomosis with the lingual artery of the tongue (Fig. 14-9A).

The mylohyoid nerve, a small branch of the mandibular nerve, rather than entering the mandibular foramen with the rest of the nerve, travels anteriorly in the mylohyoid groove on the lingual surface of the mandible (Mg in Fig. 14-6A). The mylohyoid nerve supplies the mylohyoid muscle (Fig. 14-9A,C,D), which fans out like a sling to form the functional floor of the oral cavity. This muscle inserts on the mandible along a bony ridge, the mylohyoid line (Ml in Fig. 14-6A). This line acts as a landmark, separating the oral cavity from the suprahyoid portion of the neck. Inferior to the mylohyoid muscle is the submandibular fossa (S in Fig. 14-6A), a slight concavity in the mandible for the submandibular gland. A small portion of the gland wraps around the posterior aspect of the mylohyoid muscle to enter the sublingual space (Fig. 14-9A). Superior to the mylohyoid line and muscle is the sublingual fossa (Sl in Fig. 14-6A), in which is situated the sublingual gland (Fig. 14-9A).

Also above the mylohyoid muscle are the geniohyoid and genioglossus muscles, which insert on a midline bony protuberance called the genial tubercle (Gt in Figs. 14-6B and 14-11C). It has four bony spines, two superior ones for the right and left genioglossus muscles and two inferior ones for the right and left geniohyoid muscles (Figs. 14-9C,D and

The lingual root of the left first molar is not seen in this plane. **C**, Cross-sectional views demonstrating the radicular cyst surrounding the root apex.

VIEW IMAGE

14-11C). Inferior to the mylohyoid muscle and to either side of the genial tubercle are the digastric fossae (D in Fig. 14-6A,B), each for the origin of the anterior belly of the digastric muscle (Fig. 14-9A).

The temporalis muscle (Fig. 14-9B) inserts on the coronoid process, the most superoanterior extension of the mandibular ramus (Cp in Fig. 14-6A,C). From here this muscle runs deep to the zygomatic arch to flare out over the lateral surface of the calvarium. Its function is to elevate the mandible, thus closing the jaw. Between the coronoid process and the more posterior articular condyle is the mandibular notch (Mn in Fig. 14-6C). The lateral pterygoid muscle (Fig. 14-9B) inserts on the anterior aspect of the condyle (Lp in Fig. 14-6C; Fig. 14-9D) and depresses, protrudes, and moves the jaw from side to side. The medial pterygoid (Fig. 14-9B) inserts more inferiorly on the angle of the mandible near the junction of the body and ramus (Mp in Fig. 14-6A; Fig. 14-9D) and serves to close the mandible along with the temporalis muscle.

Buccal Surface

On the buccal surface a bony ridge, the oblique line (O in Fig. 14-6C), is formed where the coronoid process (Cp in Fig. 14-6C) merges with the body of the mandible. The buccinator muscle (Fig. 14-9B), which compresses the cheeks to hold food between the teeth, inserts between the oblique line and the more medially (lingually) situated alveolar process (B in Fig. 14-6C; Fig. 14-9D). The deep and superficial portions of the masseter muscle (Fig. 14-9B,D) insert on the buccal surface of the ramus (Mm in Fig. 14-6C; Fig. 14-9D), having originated from the inferior and medial aspect of the zygomatic arch. This muscle acts to close the jaw along with the medial pterygoid and temporalis muscles. Portions of the platysma muscle also insert on the buccal aspect of the mandible along a line that runs inferiorly from the region of the molars to the mental protuberance (Fig. 14-9D). Anteriorly, between the first and second premolar teeth, the mental foramen is identified (M in Fig. 14-6C).

Superior Surface

The alveolar process, which houses the teeth, forms the most superior portion of the mandibular body. Its curved, or horseshoe, configuration is more acute than that of the body itself. This causes the alveolar process in its posterior (distal) aspect to be medially (lingually) positioned in relation to the mandibular body (Fig. 14-6D). The cross-sectional DentaScan images nicely illustrate how the alveolar process is situated on the lingual aspect of the mandible in image 10 (lower right) of Figure 14-10D.

Posterior to the teeth, the alveolar process tapers to form the retromolar triangle (Rt in Fig. 14-6D) that merges with

Copyright © 2003, Mosby, Inc. All rights reserved.

the lingual aspect of the ramus to form the temporal crest (T in Fig. 14-6D). Buccal to this, the anterior portion of the coronoid process (Cp in Fig. 14-6D) merges with the body of the mandible to form the oblique line (O in Fig. 14-6D). Between the oblique line and the temporal crest lies the retromolar fossa (Rf in Fig. 14-6D). The lateral pterygoid muscle inserts on the anterior lingual aspect of the condyle (Lp in Fig. 14-6D).

CT Images: Cross-Sectional View

Lingual Surface

Cross-sectional images 1 through 5 in Figure 14-10 are through the distal aspect of the right mandible, near the junction of the ramus and body. The mandibular foramen (Mf), the lingula (L), and the mylohyoid groove (Mg) are clearly seen on these images. More anteriorly (images 9

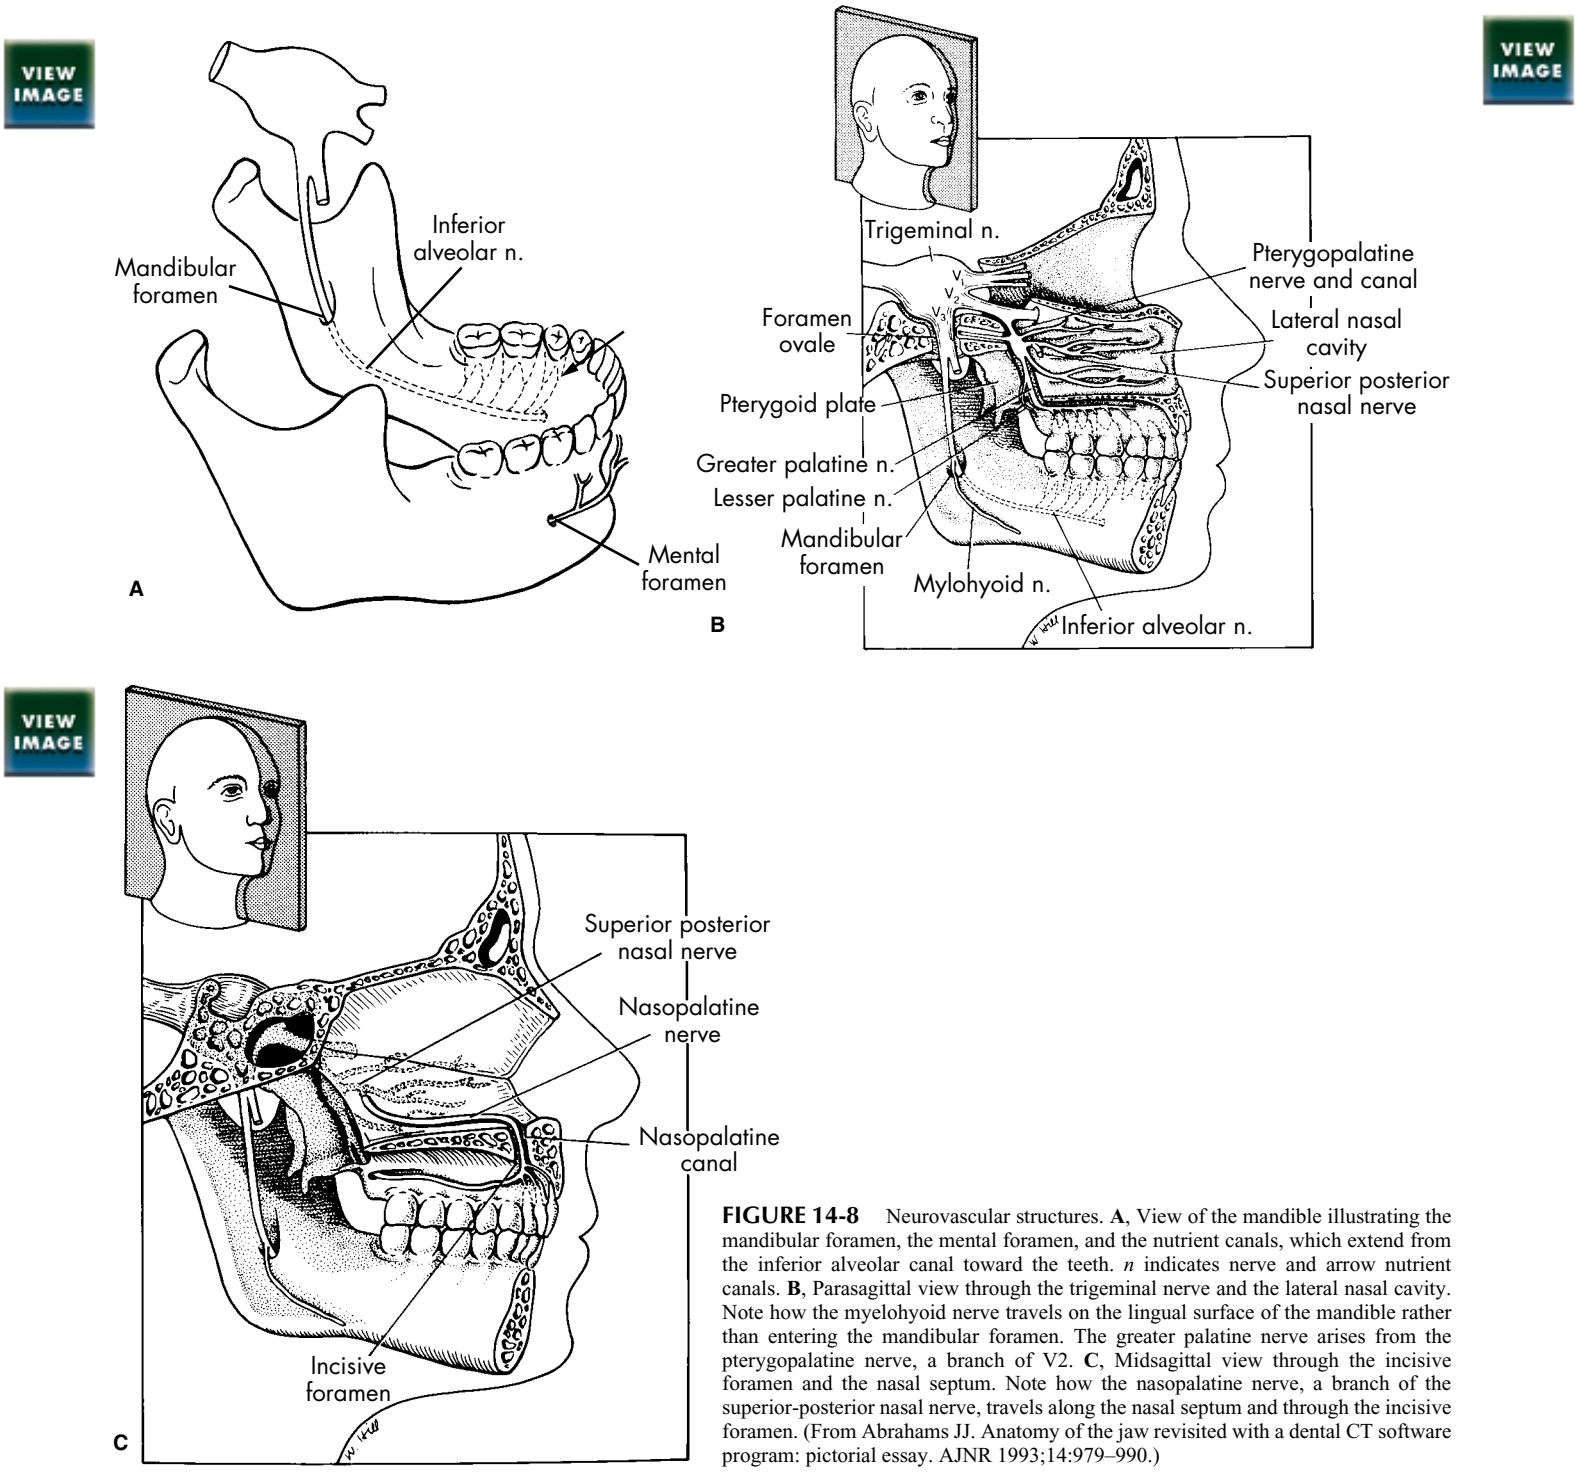

FIGURE 14-8 Neurovascular structures. **A**, View of the mandible illustrating the mandibular foramen, the mental foramen, and the nutrient canals, which extend from the inferior alveolar canal toward the teeth. *n* indicates nerve and arrow nutrient canals. **B**, Parasagittal view through the trigeminal nerve and the lateral nasal cavity. Note how the myelohyoid nerve travels on the lingual surface of the mandible rather than entering the mandibular foramen. The greater palatine nerve arises from the pterygopalatine nerve, a branch of V2. **C**, Midsagittal view through the incisive foramen and the nasal septum. Note how the nasopalatine nerve, a branch of the superior-posterior nasal nerve, travels along the nasal septum and through the incisive foramen. (From Abrahams JJ. Anatomy of the jaw revisited with a dental CT software program: pictorial essay. AJNR 1993;14:979–990.)

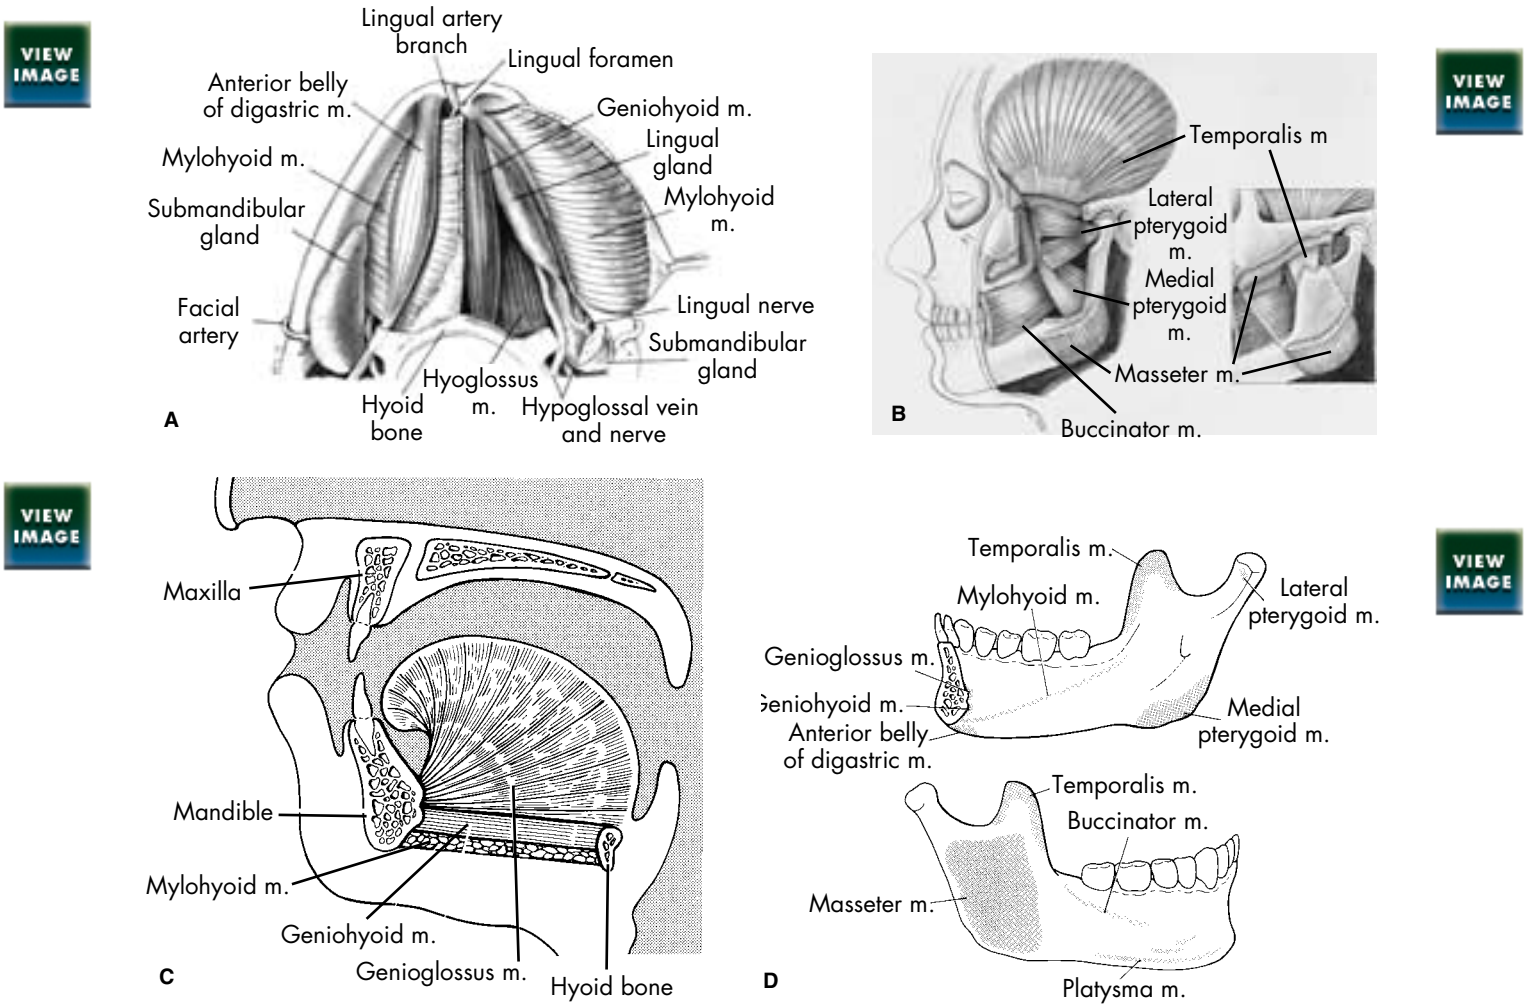

FIGURE 14-9 Muscles and insertions. **A**, Mandible viewed from below. *m* indicates muscle. **B**, Lateral view with zygomatic arch and coronoid process removed. **C**, Midline sagittal view through the genial tubercle. **D**, Muscle insertions. Lingual surface (*upper figure*). Buccal surface (*lower figure*). (From Abrahams JJ. Anatomy of the jaw revisited with a dental CT software program: pictorial essay. AJNR 1993;14:979–990.)

through 11 in Fig. 14-10D,E), the mylohyoid line (Ml), the submandibular fossa (S), and the sublingual fossa (Sl) are identified. In the region of the midline (images 27 and 28 in Fig. 14-10F), the genial tubercle (Gt) and the digastric fossa (D) can be seen. The superior (Gt-g) and inferior (Gt-h) processes of the genial tubercle, where the genioglossus and geniohyoid muscles insert, are better visualized in Figure 14-11C. This figure also demonstrates the lingual foramen (Lf) just below the genial tubercle.

Buccal Surface

The oblique line (O) that is formed where the coronoid process (Cp) merges with the body of the mandible is seen in the posterior images (images 4 through 7 in Fig. 14-10D). More anteriorly (image 20 in Fig. 14-10E), the mental foramen (M) can be seen in cross section. The course of the neurovascular bundle can be clearly traced on the cross-sectional images as it enters the mandibular foramen on the lingual surface, travels through the inferior alveolar canal (I), and finally exits the mental foramen on the buccal surface.

Superior Surface

On the buccal aspect of the superior surface, the coronoid process (Cp) is again visualized on the more distal images in Figure 14-10D. On more anterior images, the coronoid process merges with the mandible to form the oblique line (O) seen in image 7 of Figure 14-10D. On the lingual aspect of the superior surface, the temporal crest (T) is visualized on the more distal images (image 6 in Fig. 14-10D). More anteriorly the temporal crest becomes the retromolar triangle (Rt in image 8, Fig. 14-10D), and finally the alveolar process (A in image 10, Fig. 14-10D). The molars, which are normally seen in the alveolar process at this point, are absent in this edentulous patient. In the posterior mandible the alveolar process assumes a more lingual position in relation to the body of the mandible. This can be appreciated by comparing the position of the alveolar process to that of the mandible in image 10 (Fig. 14-10D) and image 17 (Fig. 14-10E). The retromolar fossa (Rf in Fig. 14-10D) is identified between the oblique line and the temporal crest.

Internal Anatomy

Internally the inferior alveolar canal (I) is seen from its origin at the mandibular foramen to its termination at the mental foramen (M). From the region of the mental foramen, a smaller canal, the canal for the incisive artery (Ia), can be seen extending toward the midline (Fig. 14-11B). On the cross-sectional images, the canal distal to the mental foramen is the inferior alveolar canal and the canal mesial to the mental foramen is the canal for the incisive artery (Fig. 14-11A,B). In the midline, the canal for the incisive artery exits the lingual foramen (Lf in Fig. 14-11C) to anastomose with the lingual artery.

Axial View

On the axial view, the genial tubercle (Gt), mental foramen (M), and inferior alveolar canal (I) are identified in Figure 14-10A,B.

Panoramic View

On the panoramic view, the course of the inferior alveolar canal (I in Fig. 14-10C and i in Fig. 14-11A) can be traced to its exit point, the mental foramen (M). The canal for the incisive artery (Ia) is visualized extending from the mental foramen toward the midline in Figure 14-11A. Also in Figure 14-11A, nutrient canals (black and white arrows) can be seen extending cephalad from the inferior alveolar canal (i) toward the teeth.

MAXILLA

The anatomy of the maxilla is described first on the anatomic specimen in Figure 14-12 and then on the illustrations of the neurovascular structures in Figure 14-8.[7–15] This anatomy is then identified on the axial,

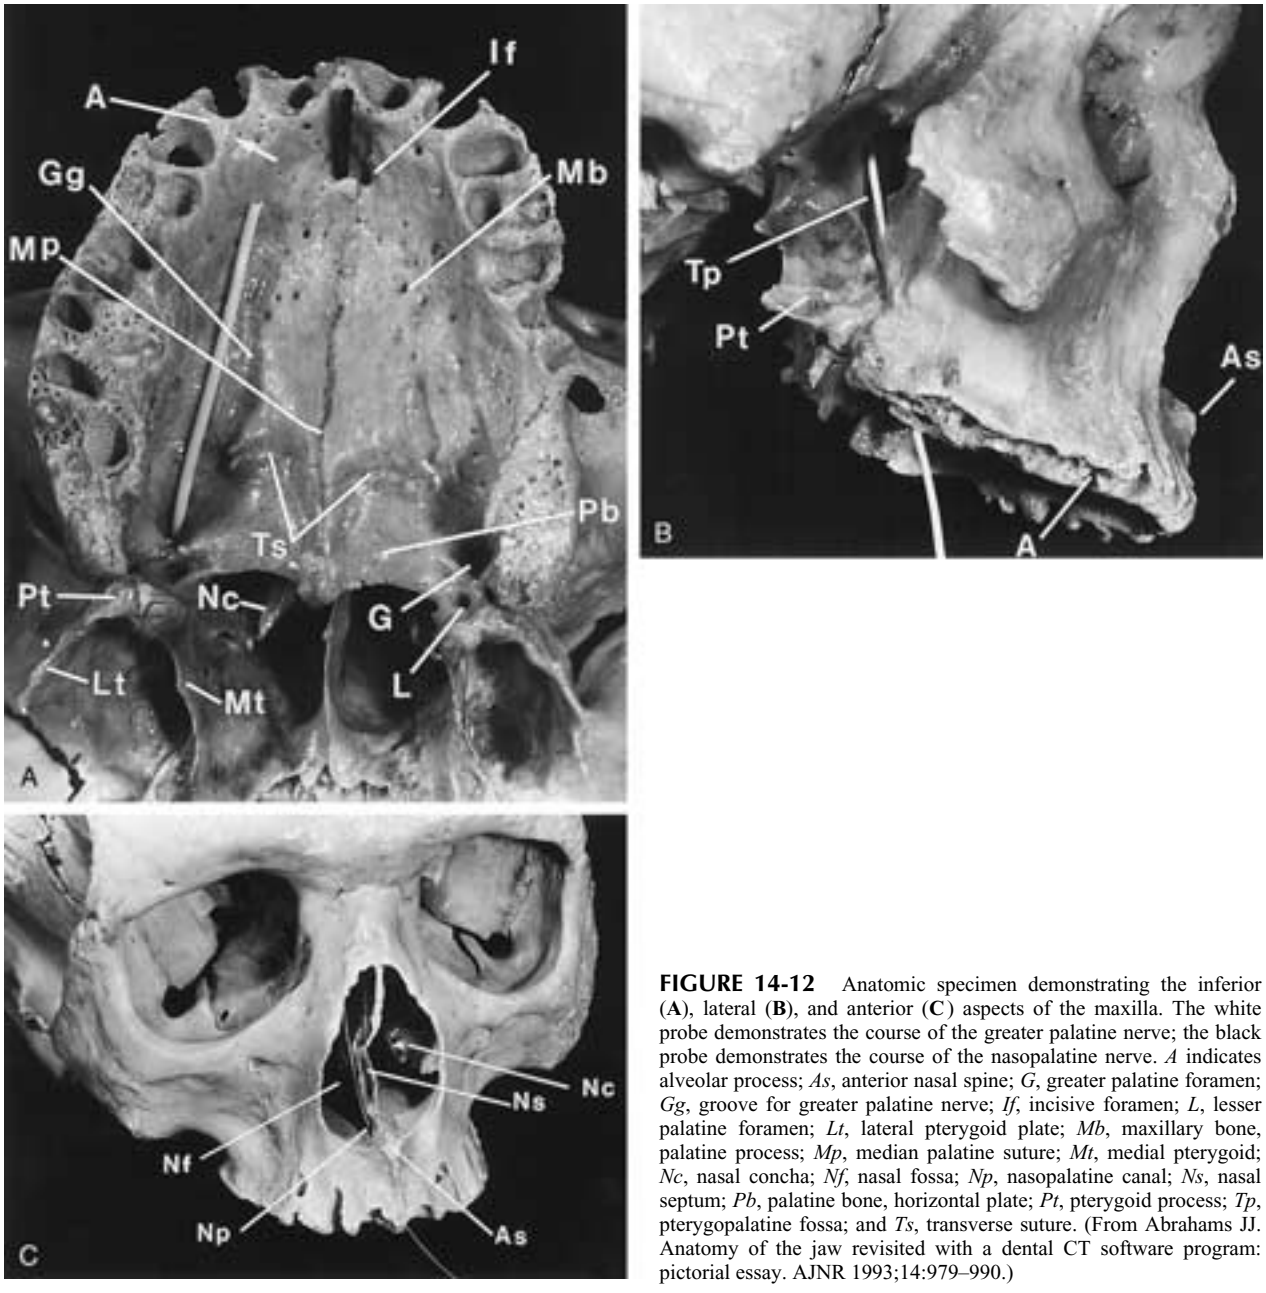

FIGURE 14-12 Anatomic specimen demonstrating the inferior (**A**), lateral (**B**), and anterior (**C**) aspects of the maxilla. The white probe demonstrates the course of the greater palatine nerve; the black probe demonstrates the course of the nasopalatine nerve. *A* indicates alveolar process; *As*, anterior nasal spine; *G*, greater palatine foramen; *Gg*, groove for greater palatine nerve; *If*, incisive foramen; *L*, lesser palatine foramen; *Lt*, lateral pterygoid plate; *Mb*, maxillary bone, palatine process; *Mp*, median palatine suture; *Mt*, medial pterygoid; *Nc*, nasal concha; *Nf*, nasal fossa; *Np*, nasopalatine canal; *Ns*, nasal septum; *Pb*, palatine bone, horizontal plate; *Pt*, pterygoid process; *Tp*, pterygopalatine fossa; and *Ts*, transverse suture. panoramic, and cross-sectional CT images in Figures 14-13 and 14-14.[17]

Anatomic Specimen

The hard palate is composed of several bones delineated by sutures. The transverse suture (coronally oriented Ts in Fig. 14-12A) separates the horizontal plate of the palatine bone (Pb in Fig. 14-12A) from the palatine process of the maxillary bone (Mb in Fig. 14-12A). The median palatine suture (Mp in Fig. 14-12A), which runs in an anteroposterior (sagittal) direction, divides the palate into right and left halves. The pterygoid process of the sphenoid bone (Pt in Fig. 14-12A) is just posterior to the alveolar process. In younger patients, a coronally oriented suture also separates the premaxilla from the maxilla. This suture extends from the incisive foramen (If in Fig. 14-12A) to the lateral incisor-cuspid region (arrow in Fig. 14-12A).

As in the mandible, the teeth are housed in the alveolar process (A in Fig. 14-12A), a horseshoe-shaped bony process in the periphery of the anterior and lateral aspects of the hard palate. Cephalad to the alveolar process are the maxillary sinuses posteriorly and the nasal fossa anteriorly (Nf in Fig. 14-12C). Within the nasal fossa the nasal conchae (Nc in Fig. 14-12C) and nasal septum (Ns in Fig. 14-12C) are seen. A bony protuberance, the anterior maxillary spine (As in Fig. 14-12B,C), is situated just below the nasal fossae in the midline.

Posterior to the maxillary sinus and between it and the pterygoid process (Pt in Fig. 14-12A,B) lies the pterygopalatine fossa (Tp in Figs. 14-12B and 14-14C). The maxillary branch (V2) of the trigeminal nerve enters the pterygopalatine fossa after exiting the skull base through the foramen rotundum. From here a branch, the pterygopalatine nerve (Fig. 14-8B), travels inferiorly through the pterygopalatine canal to exit the greater (G in Fig. 14-12A) and lesser (L in Fig. 14-12B) palatine foramina as the greater and lesser palatine nerves. In Figure 14-12A, a white probe, representing the greater palatine nerve, is seen exiting the greater palatine foramen. After exiting, this nerve changes from a craniocaudal direction to run anteromedially (and horizontally) in a groove (Gg in Fig. 14-12A) in the hard palate. As it travels in the groove, sensory fibers are given off to supply the posterior two-thirds of the hard palate and teeth. The pterygopalatine nerve, represented by the other end of the white probe in Figure 14-12B, can be traced back into the pterygopalatine fossa (Tp in Fig. 14-12B).

Another branch of the pterygopalatine nerve, the superior posterior nasal nerve (Fig. 14-8B,C), enters the posterior nasal cavity through the sphenopalatine foramen. From here it gives off the nasopalatine nerve, a medial branch that runs anteroinferiorly along the nasal septum to enter the nasopalatine canal and incisive foramen (Figs. 14-8C and 14-12C). The incisive foramen is readily seen as a small, round opening in the hard palate just posterior to the central incisors (If in Fig. 14-12A). Sensory fibers supply the anterior hard palate and, along with the anterior superior alveolar nerve (a branch of the infraorbital nerve), supply the

central teeth. The terminal portions of the nasopalatine nerve anastomose with the terminal portion of the greater palatine nerve. In Fig. 14-12A,C, the black probe represents the course of the nasopalatine nerve. Note how the black probe enters the incisive foramen (If in Fig. 14-12A), travels through the nasopalatine canal (Np in Fig. 14-12C), and then along the nasal septum (Ns in Fig. 14-12C) to merge with the superior posterior nasal nerve (Fig. 14-8C). The right and left nasopalatine canals are situated in the anteroinferior nasal fossa on either side of the nasal septum.

CT Images

Axial View

The more caudal axial images in Figure 14-14B demonstrate the alveolar process (A), incisive foramen (If), and anterior maxillary spine (As). The teeth, which are normally visualized in the alveolar process at this level, are not seen in this edentulous patient. In the more cranial images the maxillary sinus (Ms) is visible cephalad to the posterior aspect of the alveolar ridge, and the nasal fossa (Nf) is seen cephalad to the anterior aspect of this ridge (Fig. 14-14B). The nasal septum (Ns), nasal concha (Nc), and nasopharynx (N) are visualized in Figure 14-14C. Figure 14-13 illustrates how the right and left nasopalatine canals appear as two separate openings on the more superior cuts but fuse to form a common opening, the incisive foramen, on the inferior images. This is also readily seen on the panoramic view (Fig. 14-14D).

The sutures are identified at the level of the hard palate (Fig. 14-14B). The maxillary bone (Mb) is separated from the palatine bone (Pb) by the transverse suture (Ts). The median palatine suture (MP) separates the right and left halves of the palatine bones. Also seen at the level of the hard palate is the groove for the greater palatine nerve (Gg). Just cephalad to the hard palate (Fig. 14-14C) the greater (G) and lesser (L) palatine foramina are seen.

If the greater palatine foramen is followed cephalad, it merges with the pterygopalatine fossa (Tp) (Fig. 14-14C), which is situated between the posterior wall of the maxillary sinus and the pterygoid process.

Panoramic View

The panoramic view in Figure 14-14D illustrates the position of the maxillary sinuses (Ms) and nasal fossae (Nf) just cephalad to the alveolar process (A). On either side of the nasal septum (Ns), the right and left nasal palatine canals (Np) are clearly visualized merging with the more inferior incisive foramen (If).

Cross-Sectional View

In Figure 14-14E,F, images 1 through 25 correspond to the right half of the maxilla, images 26 and 27 represent the midline with the incisive foramen, and images 28 through 30 represent the more medial aspect of the left maxilla. This may be more readily appreciated by looking at perpendicular lines 1 through 30, which are superimposed on the axial image in Fig. 14-14A. In the right posterior maxilla (Fig. 14-14E), the greater palatine foramen is visualized (G in image 2). As one moves toward the midline, the most proximal portion of the groove (Gg) for the greater palatine nerve can be seen in images 3 through 5. The maxillary sinuses (Ms) are visualized cephalad to the alveolar process on the more posterior images, and the nasal fossae (Nf) are visualized cephalad to the alveolar process on the more anterior images (21 to 23 in Fig. 14-14F). In the midline (images 26 and 27, Fig. 14-14F), the nasopalatine canal (Np), incisive foramen (If), and anterior maxillary spine (As) are seen.

Edentulism is present in almost half of the population that is between 45 and 74 years of age.[1] Traditionally, edentulism has been treated with removable dentures; however, not all patients are candidates for dentures, and many have continued difficulty with speech, oral function, and reduced self-esteem. In response to these problems, dentists developed nonremovable bridges that are attached to oral implants, metal posts surgically embedded in the jaw (Fig. 15-1). During the past decade, it has been determined that CT, with a dental reformatting program, is the method of choice for the preoperative assessment of these patients, and as a result of this work, new dialogues and interactions have been created between the radiologist and the dentist and oral surgeon. This, in turn, has brought new territories and unfamiliar diseases to the radiologist's attention. Radiologists now evaluate the dental aspects of the oral cavity, including implants, periodontal disease, odontogenic tumors, and other lesions of the jaw.[2–8] The goal of this chapter is to present a comprehensive discussion of dental imaging, including dental CT reformatting programs, and orthopantomographic and intraoral films.

DENTAL CT PROGRAMS

Dental CT programs use thin, 1-mm axial CT images of the maxilla and mandible to reformat a series of multiple cross-sectional and panoramic images of the jaw. The orientation of the cross-sectional images, which can be confusing, is illustrated in Figure 15-2. The cross-sectional and panoramic images are illustrated in Figure 15-1. After the patient is scanned and the axial images have been acquired, the reformatting program is run to produce the panoramic and cross-sectional views described below.

Scan Parameters

The thin axial images are obtained in the following fashion. First, the patient is placed supine in the gantry, using a head holder, chin strap, and sponges on either side of the head to prevent motion. The patient is then instructed to remain motionless. A lateral digital scout view is first obtained to define the upper and lower limits of the study and to determine if the scan plane is parallel to the alveolar ridge. Because the DentaScan program does not permit angulation of the gantry, if the scan plane is not correctly positioned the patient should be repositioned and a repeat lateral digital scout scan performed. Once the scan plane is correct, 1-mm contiguous scans are obtained using a bone algorithm, dynamic mode, 15-cm field of view, 512 × 512 matrix, 140 kV and 70 mA. If both the mandible and maxilla are being studied, a separate run should be performed for

VIEW IMAGE

FIGURE 15-1 View of the mandible illustrating the plane of orientation of the cross-sectional DentaScan images. The top of the plane (*curved arrow*) corresponds to one of the numbered perpendicular lines on the axial image in Figure 15-2A. Note how the height and width of the alveolar process and the location of the mandibular canal can be readily determined on the cross-sectional image. Three root form implants are seen (*arrowheads*) supporting a four-tooth prosthesis. The abutment (*thin arrow*) attached to the fixture (*broad arrow*) raises it above the surface of the bone and gingiva and into the oral cavity. Inferior alveolar canal (*i*), mental foramen (*m*). (From Langer B, Sullivan D. Osseointegration: its impact on the relationship of periodontics and restorative dentistry. Part 1. Int J Periodont Res 1989;9:86.)

each because the scan angle of the mandible is slightly different than that of the maxilla.

Running the Dental Program

Once the axial images are acquired, they are processed with the dental CT reformatting program. Programs may vary slightly from manufacturer to manufacturer; however, the following guidelines generally apply. An axial image that nicely shows the curve of the mandible or maxilla at the level of the roots of the teeth is selected by the technologist and a curved line, along the midportion of the alveolus, is superimposed on the axial image (Figs. 15-2A and 15-3A) by depositing the cursor on approximately six different points along the curve of the jaw. The program then automatically connects these points to produce a smooth curve that will be superimposed on the jaw. This curved line defines the plane and location of the reformatted panoramic images (Figs. 15-2C and 15-3D). Several images are then reformatted both buccally and lingually to this curve.

The reformatted cross-sectional images (Figs. 15-2D–F and 15-3E,F) are defined by multiple numbered lines that the program automatically deposits perpendicular to the curved line (Figs. 15-2A and 15-3A). Figure 15-2A shows the plane and orientation of the cross-sectional images and the distance between the numbered perpendicular lines. The distance between the cross-sectional images can be varied. In general, a 2-mm spacing is used. If a stent with radiographic markers is utilized, 1-mm slices may be necessary to visualize the markers. The mandibular canal (neurovascular bundle) is easily visualized on the cross-sectional images, and the width and contour of the jaw can be readily assessed (Fig. 15-2D–F). Streak artifact, which degrades visualization of bone on direct coronal images, does not degrade the reformatted cross-sectional images because the artifact is projected at the level of the crowns of the teeth and not over the bony alveolus (curved arrow in Fig. 15-2E).

When the program is completed, three types of images are displayed: axial, cross-sectional, and panoramic. Typically there are approximately 30 to 50 axial images, 40 to 100 cross-sectional images, and 5 panoramic images. It is important to film these images in a consistent fashion to avoid confusing the referring dentist. Life-size (one to one magnification) cross-sectional and panoramic images are preferred. This can usually be accomplished with most programs by filming four images on a 14 × 17-inch x-ray film. If this cannot be accomplished, the manufacturer of the program should be consulted. A millimeter scale displayed on the films (mm at the bottom of Fig. 15-2D) is used to verify the degree of magnification and to obtain accurate measurements. One can place calipers on the bone image to be measured and transfer this caliper setting to the millimeter scale. Any minification or magnification of the images equally minifies or magnifies the scale and thus does not affect the measurements.

Optimally, filming is done on a laser printer. Most often the axial images are filmed with 12 images per film, while the cross-sectional and panoramic images are filmed with 4 images per film. Each cross-sectional and panoramic image actually contains multiple images (see Fig. 15-2). The images are typically photographed at a width (window) of 3000 to 4000 and a level (center) of 300 to 500 (Figs. 15-2 and 15-3).

Interpretation of Dental CT Program Images and Measurements

An understanding of the anatomy and pathology of the jaw is necessary to appropriately interpret the images displayed by the dental CT programs. It should first be noted that each CT view can be related to the others by a series of scale marks that appear on the films. The marks that run along the side of the cross-sectional and panoramic images (Fig. 15-2C,D) correspond to the direct axial slices that were used to reformat the images. For example, in Figure 15-2, 42 axial images were obtained to reformat the images; thus there are 42 scale marks along the side of the reformatted cross-sectional (Fig. 15-2D) and panoramic (Fig. 15-2C) images. The marks along the bottom of the panoramic images (Fig. 15-2C) correspond to the numbered cross-sectional images. The numbered scale lines correspond to the numbered lines drawn perpendicular to the curve superimposed on the axial image in Figure 15-2A. They therefore also correspond to the numbered cross-sectional images in Figure 15-2D–F. To illustrate how one view can be related to another, note how the right mental foramen (M) in Figure 15-2E, which is seen on cross-sectional image 20 (lower right) at the level of the fourteenth scale mark on the side of the image, is also seen in Figure 15-2B on axial image 14 at the twentieth perpendicular line. The same process can be applied to the panoramic view.

When the scan is performed as part of the preoperative workup of a dental implant patient, the status of the dentition and the proposed implant sites must be established. It should

Copyright © 2003, Mosby, Inc. All rights reserved.

be stated whether the patient is completely or partially edentulous and, if partially edentulous, where the teeth are absent. In the partially edentulous patient, it is presumed that the implants will be placed in the edentulous segments; thus measurements are obtained in these regions. The measurements are obtained from the cross-sectional images at about 10-mm intervals. If the cross-sectional images are 2 mm apart, then measurements are made on every fifth cross-sectional image. If the cross-sectional images are 1 mm apart, measurements are provided for every tenth image. The

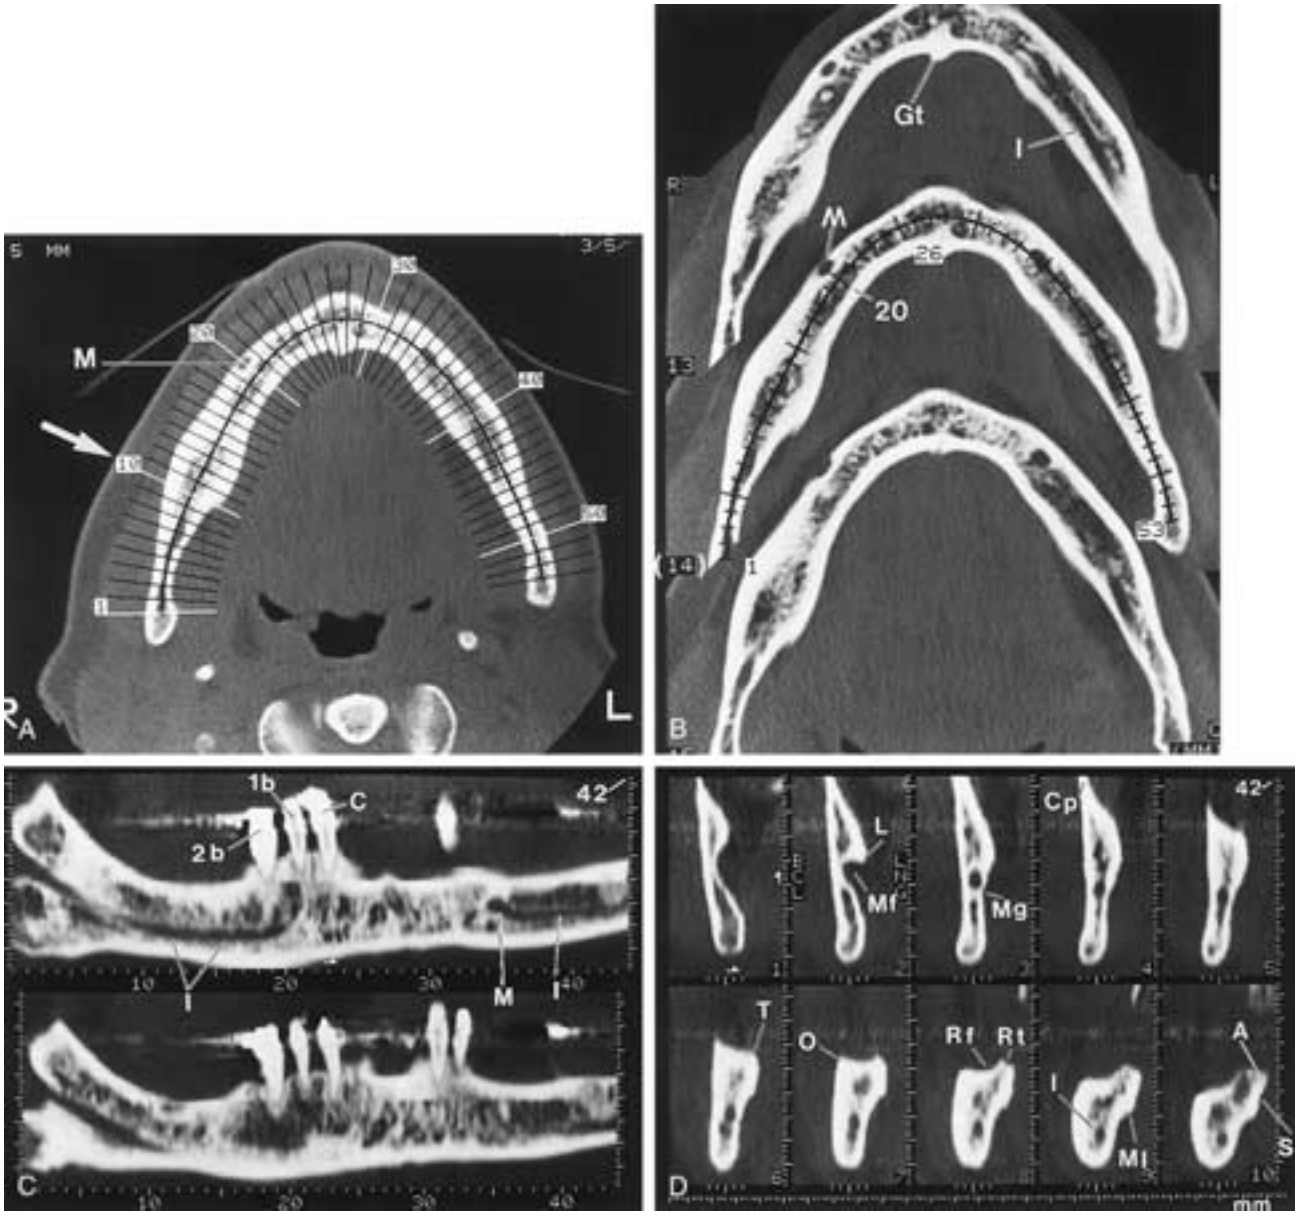

FIGURE 15-2 CT (DentaScan) scan of the mandible. The anatomy identified on the mandibular anatomic specimen in Figure 14-6 is now identified on these CT images. **A**, Axial image of mandible with a superimposed curve. The curve defines the plane and location in which the panoramic images in **C** are reformatted. Numbered lines drawn perpendicular to this curve (*arrow*) define the plane and location in which the cross-sectional images viewed in **D** through **F** are reformatted. Mental foramen (*M*). **B**, Axial images illustrating the inferior alveolar canal (*I*), the mental foramen (*M*), and the genial tubercle (*Gt*). The numbers along the left side of the figure refer to the particular number of the axial image. Note that the mental foramen, which is seen on axial image number 14 at the twentieth perpendicular line, is also seen in **E** on cross-sectional image 20 (lower right) at the level of the fourteenth tick mark on the side of the image. The tick marks and numbers allow images to be correlated with one another. **C**, Panoramic views. The numbered tick marks along the bottom of the images correspond to the numbered perpendicular lines displayed on the axial image in **A**. The tick marks along the side of the image correspond to the axial images that were used to reformat these images. Note that there were 42 axial images acquired and thus 42 tick marks along the side of this image. Inferior alveolar canal (*I*), mental foramen (*M*), second bicuspid (*2b*), first bicuspid (*1b*), and cuspid (*C*). **D** through **F**, Cross-sectional views. Images 1 through 10 (**D**) are through the posterior right mandible (see perpendicular lines 1 through 10 in **A**).

FIGURE 15-2 *Continued.* Images 11 through 20 (**E**) are more anterior. Images 21 through 30 (**F**) extend to the midline. The images of the left half of the mandible are not shown. Arrowheads in image 17 (**E**) indicate that the height of the mandible distal to the mental foramen is measured from the top of the alveolar process to the top of the mandibular canal, and mesial to the foramen it is measured from the top of the alveolar process to the bottom of the mandible (*arrowheads* in **F**, image 30). Measurement of the width is also demonstrated in image 30 (**F**). *mm* at the bottom of **D** indicates the millimeter scale. Note how streak artifact from the dental restoration (*curved arrow* in **E**) does not degrade visualization of the bone. *A* indicates alveolar process; *C,* cuspid; *Cp,* coronoid process; *D,* digastric fossa; *Gt,* genial tubercle; *I,* inferior alveolar canal; *M,* mental foramen; *Mf,* mandibular foramen; *Mg,* mylohyoid groove; *Ml,* mylohyoid line; *O,* oblique line; *Rf,* retromolar fossa; *Rt,* retromolar triangle; *S,* submandibular fossa; *S1,* sublingual fossa; *T,* temporal crest; *1b,* first bicuspid; and *2b,* second bicuspid. (From Abrahams JJ. Anatomy of the jaw revisited with a dental CT software program: pictorial essay. AJNR 1993;14:979–990.)

height and width of the alveolar process are measured as described in the following paragraph.

In the mandible, the height in the region distal (posterior) to the mental foramen is measured from the top of the alveolar process to the top to the mandibular canal (Fig. 15-2E, arrowheads in image 17). Methods of locating the mandibular canal, if it is not initially visualized on the cross-sectional images, are discussed later. In the region mesial (anterior) to the mental foramen, the full height of the mandible is obtained because the mandibular canal ends at the mental foramen and thus it is not present mesial to the foramen. Measurements in this area are provided from the top of the alveolar ridge to the bottom of the mandible (Fig. 15-2F, arrowheads in image 30). The width is measured near the top of the alveolar process (Fig. 15-2F, arrowheads in image 30). Occasionally, if the alveolar process comes to a point secondary to atrophy, it may be difficult to obtain a measurement. In this situation the surgeon may choose to remove the top pointed portion of the ridge (alveoloplasty), providing a broad base for an implant. This obviously affects the height of the alveolar ridge, and it is best to let the surgeon estimate how much of the ridge will be removed. Often under these circumstances, one simply states that the ridge is pointed, and a measurement for the width is not provided.

In the maxilla, the height in the distal (posterior) aspect is measured from the top (inferior surface) of the alveolar process to the floor of the maxillary sinus (Fig. 15-3E, arrows in image 7). More mesially (anteriorly), the height is usually not limited by the maxillary sinuses and is measured from the alveolar ridge to the nasal fossa floor (Fig. 15-3F, arrows in image 23). The width is measured in the same manner as that described for the mandible (Fig. 15-3F, arrows in image 22). In the completely edentulous patient, it is more desirable to place the implants centrally because the height of the alveolar process is not limited by the more distal mandibular canal or the maxillary sinuses.

Identifying the Mandibular Canal

It is extremely important to identify the mandibular canal on cross-sectional images and to provide the measurement from the top of the alveolar ridge to the top of this canal. If the canal is not properly identified, its injury during implant surgery can be quite debilitating for the patient, resulting in permanent paresthesia and hypesthesia of the face. Typically the canal is readily seen on cross-sectional images. However, there are times when portions of the canal or even the entire canal may be hard to visualize on the cross-sectional images. In this situation the following methods may be helpful in locating the canal.

The first method involves the cortical niche sign, which refers to an indentation along the inner or medullary margin on the lingual cortex of the mandible. This niche is created by the mandibular nerve as it traverses the mandible (Fig. 15-4). However, this niche can be quite subtle, unlike that shown in Figure 15-4, and it is not identified in all patients. When present, it is a good way to identify the canal. Care should be taken not to confuse other cortical irregularities with the cortical niche sign. The cortical niche is a continuous defect seen on multiple cross-sectional images. Other cortical irregularities are randomly situated and are not seen consecutively on multiple images. When the canal is identified with the cortical niche sign, its location should be confirmed with the other methods.

The next method, referred to as triangulation, utilizes the scale marks on the films to relate an anatomic structure well seen on one view to its location on another view. With this method, the panoramic and axial views can be

Copyright © 2003, Mosby, Inc. All rights reserved.

utilized to identify the canal on the cross-sectional views. For example, in Figure 15-5A, it is difficult to see the canal on the cross-sectional images, but the canal is readily seen in the panoramic view (Fig. 15-5B). The information from the panoramic view can be used to triangulate the location of the canal on the cross-sectional image, as shown in Figure 15-5.

To locate the canal on cross-sectional image 14 (Fig. 15-5A), first refer to the fourteenth scale mark along the bottom of the panoramic view (Fig. 15-5B). A vertical line from this point is then drawn up to the bottom of the canal and extended across in a perpendicular direction toward the scale marks on the left side of the panoramic image. Note

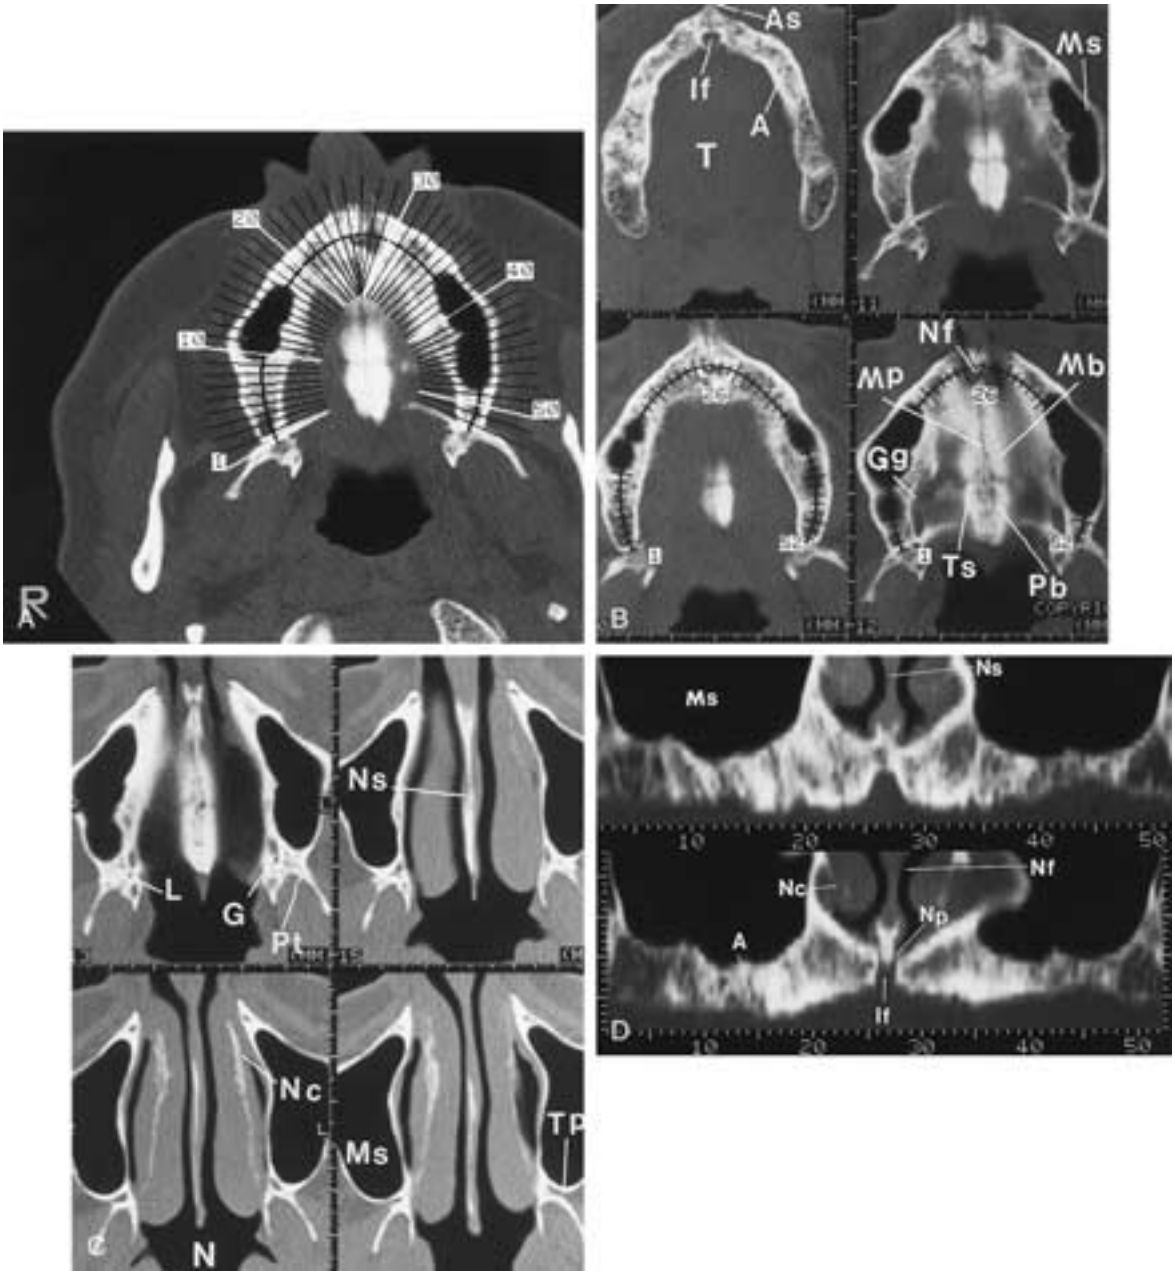

FIGURE 15-3 CT (DentaScan) scan of maxilla. The anatomy identified on the maxillary anatomic specimen in Figure 15-12 is now identified on these CT images. **A**, Axial image with superimposed curve. The curve defines the plane and location in which the panoramic images seen in **D** are reformatted. Numbered lines drawn perpendicular to this curve define the plane and location in which the cross-sectional images viewed in **E** and **F** are reformatted. **B**, Axial views through the alveolar ridge and hard palate. *A* indicates alveolar process; *As,* inferior nasal spine; *Gg,* groove for greater palatine nerve; *If,* incisive foramen; *Mb,* maxillary bone—palatine process; *Mp,* median palatine suture; *Ms,* maxillary sinus; *Nf,* nasal fossa; *Pb,* palatine bone—horizontal plate; *Ts,* transverse suture; and *T,* tongue. **C**, Axial views through the maxillary sinuses and the pterygopalatine fossa. *G* indicates greater palatine foramen; *L,* lesser palatine foramen; *Ms,* maxillary sinus; *Nc,* nasal concha; *Ns,* nasal septum; *Pt,* pterygoid process; and *Tp,* pterygopalatine fossa. **D**, Panoramic views. *A* indicates alveolar process; *If,* incisive foramen; *Ms,* maxillary sinus; *Nc,* nasal concha; *Nf,* nasal fossa; *Np,* nasopalatine canal; and *Ns,* nasal septum.

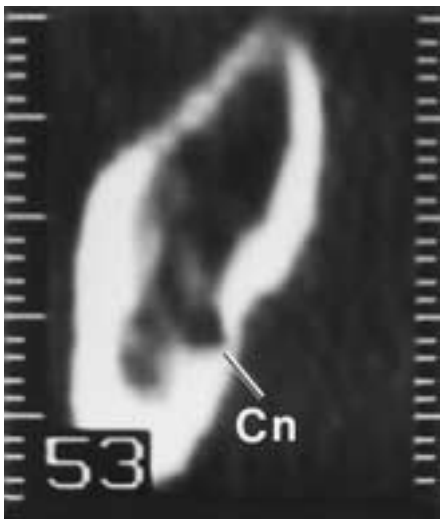
FIGURE 15-3 *Continued.* **E** and **F**, Cross-sectional views. Images 1 through 15 (**E**) are through the posterior right maxilla (see perpendicular lines 1 through 15 in **A**); images 16 through 30 (**F**) are more anterior on the right and extend to the midline (see perpendicular lines 16 through 30 in **A**). The arrows in image 7 (**E**) indicate how the height of the distal alveolar process is measured from the floor of the maxillary sinus to the top of the alveolar process and the mesial alveolar process (*F* in image 23) is measured from the floor of the nasal fossa to the top of the alveolar process (*arrows* in image 23). The arrows in image 22 (**F**) indicate how the width of the alveolar process is measured. *A* indicates alveolar process; *As,* anterior maxillary spine; *G,* greater palatine foramen; *Gg,* groove for greater palatine nerve; *If,* incisive foramen; *Ms,* maxilllary sinus; *Nc,* nasal concha; *Nf,* nasal fossa; and *Np,* nasopalatine canal. (From Abrahams JJ. Anatomy of the jaw revisited with a dental CT software program: pictorial essay. AJNR 1993;14:979–990.)

that this line intersects the twenty-first scale mark along the left side of the image. The level of the canal in cross-sectional image 14 can then be identified by counting up 21 scale marks along the side of the image (Fig. 15-5A). This same process can also be utilized with the axial images.

Finally, if a canal is identified on some cross-sectional images but not on others, the images on which it is identified can be utilized to estimate the position of the canal on the other images. This can be done because the distance from the bottom of the mandible to the bottom of the canal tends to be relatively constant. The only region where the distance is not constant is immediately adjacent to the mandibular foramen and the mental foramen. It is the distance from the top of the canal to the top of the alveolar process that varies secondary to atrophic changes. With this knowledge, one can extrapolate the location of the canal from the images in which it is visualized. For example, in Figure 15-2E, the distance from the bottom of the canal to the bottom of the mandible in image 11 is 5 mm, and in image 15 it is also 5 mm. Therefore, if the canal was not visualized in image 15, its location could be estimated by utilizing the position of the canal that was visible on image 11. Usually the right and left hemimandibles are symmetric, and the distance from the bottom of the mandible to the bottom of the canal on the right side at a particular point is approximately the same as the distance measured at that same point on the left. Thus, if the canal is identified on the cross-sectional images of the right half of the mandible, but not on the left side, this information can be used to estimate the position of the canal on the left side. It is recommended that one use several of these methods to confirm the location of the canal rather than relying on only one method.



VIEW IMAGE

FIGURE 15-4 Cortical niche sign. This cross-sectional image of the mandible demonstrates an indentation on the lingual cortex of the mandible called the cortical niche sign (*Cn*), which is created by the mandibular nerve as it traverses the mandible. This sign, which is often more subtle than this, can be helpful in identifying the location of the mandibular canal. (From Abrahams JJ. CT assessment of dental implant planning. Oral Maxillofac Surg Clin North Am 1992;4:1–18.)

Dictated Report

A complete and comprehensive report should be provided for the referring dentist or oral surgeon. First, the report usually provides a discussion of the density and general health of the jaw. Also described are the presence of such conditions as maxillary sinus disease, periodontal disease, root canal procedures, extraction sockets, retained roots, atrophy, cysts, osteitis condensans, contour irregularities, surgical changes, and anomalies such as torus palatinus or mandibu-

Copyright © 2003, Mosby, Inc. All rights reserved.

larus. Next, the status of the dentition is discussed. State whether the patient is partially or completely edentulous. If the patient is partially edentulous, state whether the edentulous area is central or distally on the right or left.

If the scan is being performed for dental implants, then measurements of the alveolar ridge are provided of the edentulous regions where the implants are likely to be placed. The measurements are taken from the cross-sectional images at about 10-mm intervals, as described above, and reported in a tabular fashion. The location of the mental foramina and incisive foramen are identified as a reference point and for easier interpretation. For example, the following measurements were obtained from Figure 15-2E,F:

Image 17: Height 14 mm, width 4 mm
Image 20: Left mental foramen
Image 25: Height 26 mm, width 4 mm

If a stent with radiopaque markers is utilized, then the markers on the images are numbered with a wax pencil, measurements are obtained on the cross-sectional images where the markers appear, and the image number is provided in the report. In Figure 15-6, the measurements at the markers are as follows:

Marker 4 (Image 21): Height 13 mm, width 6 mm
Marker 5 (Image 27): Height 12 mm, width 5 mm

If the scan was performed to evaluate a lesion rather than implant placements, the alveolar measurements are not needed. Instead, a description of the lesion is provided. Is there expansion of the jaw or destruction of the cortex? Is the lesion lytic or opaque? Is it diffuse or focal? Are the roots of the teeth displaced or eroded?

Finally, the report should end with a brief impression, describing any pertinent pathology and the degree of atrophy of the alveolar process in the case of dental implants. One should also state that ''all measurements should be verified prior to surgery.'' This statement is included because the surgeon may choose to place the implant at a somewhat different angle than that measured by the radiologist and because, when the report is transcribed, it is possible for numbers to be typed incorrectly, and this may be difficult for the radiologist to notice.

ORTHOPANTOMOGRAPHIC (PANOREX) RADIOGRAPHY

Panoramic radiography is usually performed in a dentist's office. The typical use of this modality is to provide an overview for evaluating the jaws and dentition in a single radiograph (Fig. 15-7). This technique demonstrates the relationship of the teeth to the surrounding structures. It is extremely valuable before exodontia (removal of teeth) and for evaluating mandibular fractures. Since it shows the relationships of the teeth to the other teeth and surrounding structures, it is useful in orthodontic treatment planning and for demonstrating orthodontic movement of teeth. Other situations, such as abnormally erupted teeth, extractions, relationship of tumors to teeth, and so on, can also be assessed (Fig. 15-7).

Panoramic radiography of the jaws helps overcome limitations of conventional intraoral radiography. The radiation dose to the patient is 10 times less than that of the full-mouth intraoral radiography survey. Further, it allows overall coverage of the entire dental arches and associated structures on one radiograph. There can, however, be up to 25% distortion, and measurements may therefore be difficult. This is a relatively fast and painless procedure. It is also very useful when a patient cannot open the mouth due to trismus or trauma. The mandibular ramus, styloid process, temporo-

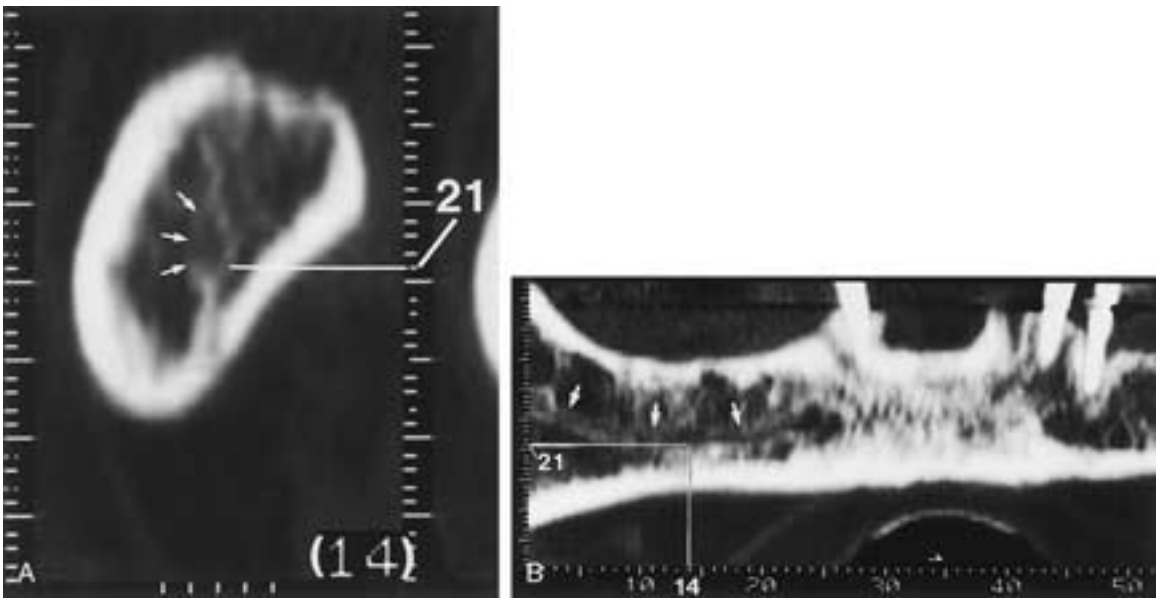


FIGURE 15-5 Triangulation. When the inferior alveolar canal is not initially seen on the cross-sectional images, as in this case (**A**), its location can be determined by triangulating from the panoramic (**B**) or axial image, as described in the section of text on ''Identifying the Mandibular Canal''. The inferior alveolar canal is indicated by arrows. (From Abrahams JJ. CT assessment of dental implant planning. Oral Maxillofac Surg Clin North Am 1992;4:1–18.)

FIGURE 15-6 Surgical implant procedure. **A**, A stent with six vertical markers has been placed over the alveolar ridge and residual teeth. The sixth marker (*long arrow*) is adjacent to the right canine (*short arrow*) and will be demonstrated on the CT images. This marker appears as a dot on the axial image and as a line on the cross-sectional image. **B**, Cross-sectional views demonstrating markers 4 (*open arrow*), 5 (*straight arrow*), and 6 (*curved arrow*) of the stent. Note that marker number 6 is adjacent to the right canine (*open curved arrow*). By placing the stent on the patient during surgery, the surgeon knows that the bone under marker 6 is as depicted by cross-sectional image 32. (From Abrahams JJ. The role of diagnostic imaging in dental implantology. Radiol Clin North Am 1993;31(1):163–180.)

mandibular joint, superior maxillary sinus, and floor of the mouth structures are visualized. These structures cannot be seen with intraoral radiography. With this technique, some soft-tissue structures attenuate the x-ray beam enough to be visualized and cause artifacts. The panoramic radiograph is limited, when compared with conventional intraoral radiography, by the necessity for careful technique, sensitivity to patient motion, and relatively poor spatial resolution.

Rotational panoramic radiographs are obtained by rotating a slender x-ray beam in a horizontal axis that is positioned extraorally. The principle is very similar to that of conventional x-ray tomography. With this technique, the focal spot of the x-ray tube anode acts as the dimension of the projection. To eliminate scatter and artifact, the x-ray beam is angled beneath the occipital condyles of the skull approximately – 4° to –7°. The patient remains stationary as the x-ray tube and film cassette holder both rotate around the patient's face during the exposure. The film is exposed though a narrow opening in the cassette that is usually flexible. These films are very technique sensitive. If the patient is improperly positioned, certain structures will be out of the focal trough (blurred). Even in properly positioned patients, the midline structures may be flattened and spread out or may be projected as a double image.

The normal anatomic structure seen in panoramic radiography are listed below and shown in Figures 15-7 and 15-8.

INTRAORAL RADIOGRAPHY

An intraoral radiograph is obtained by placing a film packet in the mouth and projecting the x-ray beam at different angles from a position outside of the mouth toward the teeth. There are three types of intraoral radiographs, which are described as periapical, bitewing, and occlusal.

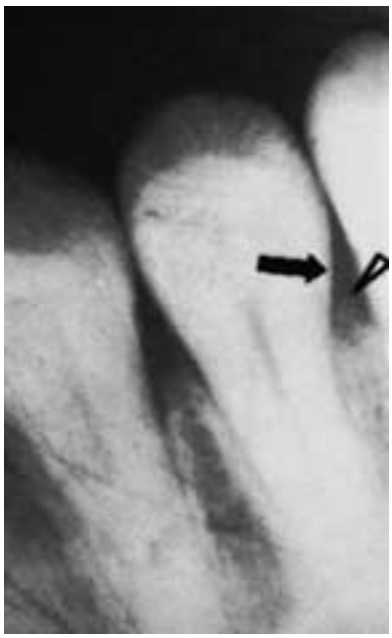
Periapical Radiographs

The word *periapical* comes from *peri,* meaning ''around,'' and *apical,* meaning ''at the apex or end of the tooth root'' (Fig. 15-9). This is the most common type of radiograph obtained in a dentist's office and has great spatial resolution, demonstrating exquisite detail compared with other techniques. Ideally, it is obtained by placing a film holder on the occlusal surface of the teeth and asking the patient to bite down to hold it in place. The film is attached to the end of the film holder within the patient's mouth on the lingual aspect, and an aiming guide is built into the other end of the film holder outside the patient's mouth. The aiming guide allows the dental x-ray tube to be aligned perpendicular to the film, thus preventing distortion. Periapical films allow the dentist to visualize the entire tooth, root, and surrounding structures, and to visualize the relationship of one tooth and its root to another. They allow the dentist to evaluate whether common entities such as caries and periodontal disease exist and, if so, their extent. This radiograph is also obtained during endodontal (root canal) procedures to measure tooth length and to determine whether the endodontal restoration (within the tooth root) is in the proper position. Periapical films have a vertical orientation, while the bitewing films have a horizontal orientation.



VIEW IMAGE

FIGURE 15-9 Periapical radiograph of mandibular first and second premolars. Cementoenamel junction (where enamel of tooth crown ends and cementum of root begins) (*black arrow*). The arrowhead points to the place where the alveolar crest of bone would normally be. Note that the bone is below this level secondary to loss from periodontal disease.

Bitewing Radiographs

Bitewing radiographs (Fig. 15-10) demonstrate on a single film the position and extent of the crowns and coronal one-third of the interalveolar bone and portion of the roots of the maxillary and mandibular teeth. These radiographs, too, have excellent spatial resolution. A special bitewing holding device is placed on the occlusal surface of the tooth and the patient gently bites down to hold it in place. As with the periapical radiograph, an aiming device is ideally used to maintain a perpendicular relationship between the film and the x-ray beam. These films are commonly obtained to detect interproximal caries (between teeth), iatrogenically malplaced dental restorations, periodontal disease, and calculus (tartar) deposits; to evaluate pulp chamber shape and size; and to evaluate the occlusal relationship of teeth. They are not usually helpful for visualization of the root apices or periapical lesions such as a cysts or abscesses.

Occlusal Radiographs

Occlusal radiographs are images of the incisal edges and occlusal surfaces of the teeth and a cross-section of the dental arches. The hard palate, upper lip, and base of the nose are seen in a maxillary occlusal radiograph. The mandibular occlusal radiograph records the floor of mouth, tongue, and lower lip. This type of radiograph is useful for determining the presence of foreign bodies, alveolar

fractures, and salivary duct calculi, as well as the position and relationship of impacted teeth.

DENTAL PATHOLOGY SEEN ON RADIOGRAPHS

Periodontal Disease

One of the most common abnormalities seen in dental radiographs is periodontal disease. This disease is a result of gingival inflammation (gingivitis), which leads to periodontitis (inflammation of the tooth socket) and then edentulism. Periodontal disease is very closely related to the patient's age and the amount of dental plaque accumulation. Accumulation of dental plaque at the free gingival margin causes the initial lesion of periodontal disease. Inflammatory exudates, gingival crevicular fluid, and leukocytes migrate into the gingival crevice. The collagen fibers within the gingiva near the free gingival margin become destroyed and replaced by inflammatory infiltrate and engorged vasculature. Subsequently, chemotactic substances from the maturing dental plaque cause a host response.

Initially, after about 4 days, early gingivitis develops, with associated swelling and erythema. Plaque then invades the periodontal ligament space, the gingival sulcus deepens through destruction of the junctional epithelium, and an inflammatory reaction against the plaque ensues at the free gingival margin. The periodontal membrane remains intact initially. After several weeks, inflammatory changes become more pronounced, and there is an increase in swelling and crevicular bleeding, with an associated increase in exudate. Predominantly plasma cells, along with T and B lymphocytes, are now found within the gingival sulcus. The lesion may exist for long periods, perhaps years, without progressing to the advanced lesion.[9]

As the lesion advances, plaque accumulates deep within the dental gingival junction, replacing the collagen fiber of the gingiva with inflamed connective tissue, ulceration of pocket epithelium, and increased crevicular fluid production. This results in destruction of the normal anatomy of the gingiva. Plaque and calculus then adhere to the root and tooth surface, attaching to irregularities in the cementum and absorbing bacterial endotoxin. Osteoclastic activity is then induced by factors from the dental plaque or inflammatory response. The supporting bone for the tooth is then lost.[10]

Some authors believe, however, that periodontal disease develops in response to infection by specific bacteria. Over 300 different microbial species have been identified that are associated with dental plaque and periodontal disease. Some, however, point to *Actinobacillus actinomycetemcomitans, Bacteroides indermedius,* and *Bacteroides gingivalis* as specific organisms that induce periodontal disease.

Most authors do agree that periodontal disease is a chronic disease that results in bone destruction (and supporting dental apparatus) at a rate of 0.2 mm per year. Some gingival plaque is thought of as inciting a host parasite response. This results in gingivitis followed by periodontal ligament attachment loss, increased gingival sulcus depth bone, and eventually tooth loss.

Normally, in the fully erupted dentition, the alveolar crest of bone is located adjacent to the cementoenamel junction of the tooth (where the enamel of the crown meets the cementum of the root). In Figure 15-9, one can see that early periodontal disease has caused the alveolar crest to be slightly below where it should be. As the disease progresses, there is more loss of bone and widening of the periodontal ligament space, which appears radiographically as a widening lucency between the bone and root (Fig. 15-11). Eventually more bone is lost, resulting in a moderate degree of disease (Fig. 15-12), and finally advanced bone loss ensues (Fig. 15-12). In addition to being focal, periodontal disease may be generalized to involve the entire maxilla or mandible.

FIGURE 15-11 Periapical radiograph of mandibular central incisors depicts mild loss of alveolar bone from periodontal disease. Alveolar crest (*arrowhead*) is eroded and is now located below the cementoenamel junction (*white arrow*). Concurrent minimal widening of the periodontal ligament space (*black arrows*) is noted.

VIEW IMAGE

Dental Caries

The next most common pathologic entity encountered on radiographs of the jaws is dental caries, an infectious disease associated with cavitation of the crown of an erupted tooth. Carious lesions are the result of mineral dissolution of the dental hard tissues by the acid metabolic products of carbohydrate fermenting bacteria. Since the enamel is composed primarily of inorganic salts, the process leads to formation of a cavity (carious lesion) due to demineralization from the altered pH. This is one of the most common diseases of humans and is more prevalent in societies that have a high percentage of processed, sugar-sweetened, sticky food. There is also a sex predilection, with a higher

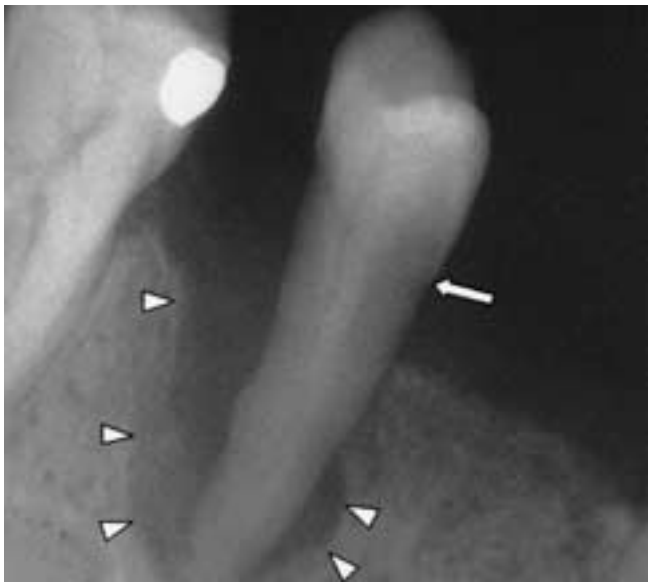
frequency in women. Dental caries are the largest cause of tooth loss in people below the age of 35.

All dental caries start at the tooth surface and can be divided into the following types: pit and fissure, smooth surface, root (cemental), and recurrent types. They may also be either acute or chronic.

Pit and fissure caries are the most common type, often appearing at an early age. *Pits and fissures* refer to the normal anatomic irregularities predominantly seen along occlusal surfaces of the posterior teeth. Fissures are also present along the buccal and lingual surfaces of the molars and, to a lesser degree, along the lingual surfaces of the anterior teeth. Pit and fissure caries typically occur on the occlusal surfaces (surface facing an opposing tooth) (Fig. 15-14) and, less commonly, on the buccal surface (facing the cheek) of the primary and secondary posterior dentition. Occasionally, the lingual surface (surface facing the tongue) may be affected.

Smooth surface caries occur on those surfaces of the teeth that are smooth, without pits and fissures. The smooth surfaces are not involved in mastication. Smooth surface caries most commonly occur in interproximal regions where contiguous teeth abut. They most frequently occur at the mesial (anterior) (Fig. 15-15) and distal (posterior) (Fig. 15-10) surfaces at the contact point with the adjacent tooth, but may also occur in the cervical region buccally or lingually. Nursing bottle caries is a type of smooth surface caries caused by leaving the feeding bottle containing milk or juice in the infant's mouth when sleeping. This is commonly seen on the labial surface of the dentition. Additionally, in adults, smooth surface carious lesions are usually secondary to alteration in the quantity or quality of saliva produced. This may also be seen with dry mouth secondary to radiation therapy.



VIEW IMAGE

FIGURE 15-15 Periapical radiograph depicts a large interproximal carious lesion of the mesial surface (*arrowheads*). Concurrent moderate loss of alveolar bone is noted (*black arrow*).

Root (cemental) caries occurs in older adults secondary to gingival recession. The exposed root surface is thin and soft, making the root vulnerable to the abrasive action of tooth brushing. Chemical erosion from bacterial acid production may also affect the root surface, causing erosion of the thin dentin layer. This may quickly invade the pulp cavity, resulting in a nonvital tooth.

Recurrent caries is a term used for caries that have formed around a dental restoration. These lesions may be due to weakness in the integrity of a restoration that results in marginal leakage. This allows food and bacteria to insinuate between the restoration and the remaining tooth structure, outside of the area that is cleaned. These lesions progress at variable speed, depending on the patient's diet, oral hygiene habits, and the degree of sclerosis of adjacent dentin.[11]

Rampant caries are often found in young patients. They occur because young teeth have large pulp chambers with short and wide dentinal tubules containing little sclerosis. When this condition is combined with a diet high in refined carbohydrates and sugars and poor oral hygiene, rapid extensive caries may develop.[12]

DENTAL IMPLANTS

Dental implants are metal posts that are surgically implanted in the jaw to support a fixed dental prosthesis (Fig. 16-1). In the early development of implants, dentists attempted to imitate the natural anchorage system of the teeth, which are attached to the bony socket by the periodontal ligament. In addition to supporting the teeth, this ligament permits slight degrees of tooth motion within the socket. This ligament is visualized on plain radiographs as a thin radiolucent line situated between the lamina dura of the jaw and the tooth. The initial efforts to reproduce this ligament promoted growth of soft tissue between the oral implant and the bone.[1] These implants were often referred to as pseudoligaments or fibrous osseointegrated implants.[2, 3] However, the long-term results of these soft tissue–anchored implants were poor, and researchers redirected their efforts toward the possibility of anchoring the implants by direct contact with bone. Early long-term studies with these osseointegrated implants were optimistic, with success rates of 91% in the mandible and 81% in the maxilla.[4] Microscopic sections through bone-containing implants demonstrated the ability of osteoblasts to grow and integrate with the titanium posts, resulting in osseointegration.[5] The results of these early studies were corroborated by others, and this paved the road for the osseointegrated implants utilized today.[6]

There are three basic types of implants: root form (Fig. 16-1), blade (Fig. 16-2), and subperiosteal (Fig. 16-3). The osseointegrated, cylinder-shaped implants described previously are the root form because they simulate the shape of the root of a tooth. They are the ones most frequently used today and will be the type dealt with in this chapter. The blade implants are rectangular and are similar in shape to a razor blade. From the long side of the rectangle, one or more posts extend into the oral cavity to permit fixation of the prosthesis. The rectangular portion is implanted into the bone via a linear osteotomy, and the posts extend up above the gingiva. Lastly, the subperiosteal implants are metallic meshes that are custom built to fit over the alveolar process and under the periosteum. Several metallic posts extend from the mesh into the oral cavity (above the gingiva) to support the prosthesis. To customize these subperiosteal implants, the alveolar process must be surgically exposed so that a plaster impression can be obtained to manufacture the implant. After the implant is manufactured, the patient returns for a second surgical procedure that permits placement of the implant. The first surgical procedure can be eliminated if thin-slice axial CT is used to produce a 3D model of the jaw from which the prosthesis can be manufactured.

Osseointegrated root form implants are made up of several components (Fig. 16-4). The fixture is the portion of the implant that is surgically embedded in the osseous tissue of the jaw. It is made of titanium, a material that promotes osseointegration. The fixtures come in various sizes, typically ranging from 3.25 to 3.75 mm in diameter and 7 to 10 mm in length.[7] The size of the implant chosen is dependent upon the amount of available jaw bone. Dentists prefer the largest possible implant because it increases the surface area and thus provides stronger anchorage and more successful osseointegration. It is also preferable to have 1 to 1.5 mm of bone on either side of the implant and 1 to 2 mm of bone between the bottom of the implant and the adjacent structures (i.e., maxillary sinus, mandibular canal).[7] Fixtures can be threaded, unthreaded, or even coated with hydroxyapatite.[8]

The next component of the implant is the abutment (Figs. 16-1, 16-4), which is attached to the fixture to increase its

FIGURE 16-1 View of the mandible illustrating the plane of orientation of the cross-sectional DentaScan images. The top of the plane (*curved arrow*) would correspond to one of the numbered perpendicular lines on the axial image in Figure 16-2A. Note how the height and width of the alveolar process and the location of the mandibular canal can be readily determined on the cross-sectional image. Three root form implants are seen (*arrowheads*) supporting a four-tooth prosthesis. The abutment (*thin arrow*) that is attached to the fixture (*broad arrow*) raises it above the surface of the bone and gingiva and into the oral cavity. Inferior alveolar canal (*i*), mental foramen (*m*). (From Langer B, Sullivan D. Osseointegration: its impact on the relationship of periodontics and restorative dentistry. Part 1. Int J Periodont Res 1989;9:86.)

height to a level above the gingival surface. This occurs 3 to 6 months after the initial procedure, thus giving the fixture time to heal within the bone. The fixture is surgically exposed, and the abutment is attached with an abutment screw (Fig. 16-4). The top of the abutment screw itself has a small screw hole, which allows the dental prosthesis to be attached by a screw that runs through the prosthesis and into the abutment screw. This screw is designed to be the weakest portion of the implant so that in the event of unforeseen stress, it, rather than the fixture, will break. Angled abutments are also available to correct for implants that are inserted at an angle rather than parallel to the residual teeth.

The prosthesis is composed of a strong metal framework (Fig. 16-4) that supports the prosthetic teeth. Because the implants actually support this framework, patients can have a full 14-tooth dental prosthesis supported by only six implants or a 3-tooth prosthesis supported by two implants, as shown in Figure 16-4.

IMPLANT SURGICAL PROCEDURE

Dental implant surgery is a usually a two-stage procedure requiring a 4- to 6-month healing period between stages.[9] The healing period allows time for osseointegration to occur. In the first stage the fixture is installed; in the second stage the fixture is exposed, and the abutment is attached. The procedures are typically performed in the dentist's office, using local anesthetic.

Fixture Placement

The first stage of surgery, fixture installation, is more extensive than the second stage and usually takes about 2

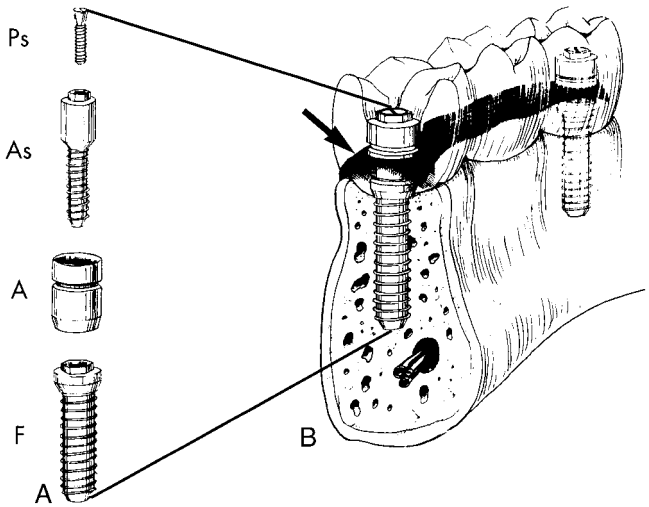
FIGURE 16-3 Subperiosteal implant. **A**, Photograph of a subperiosteal implant. The white portion fits under the periosteum and on top of the bone of the alveolar process, and the metallic-appearing portion extends above the gingiva to support the prosthesis. The subperiosteal portion (*white*) is often coated with hydroxyapatite to facilitate bone growth. **B**, Panoramic view demonstrating the subperiosteal implant on a severely atrophic mandible. The prosthesis has not been attached. (Courtesy of Dr. Wayne C. Jarvis, Williamsville, NY.)

hours, depending on the number of fixtures placed. Anesthesia is obtained by using local infiltration with lidocaine or a nerve block. A linear incision is then made along the buccal or lingual surface of the alveolar ridge, and a soft tissue flap, incorporating the periosteum, is reflected back (Fig. 16-5E). If the exposed bony ridge has a sharp or pointed surface secondary to buccolingual atrophy, an alveoloplasty may be performed to remove the sharp edge and provide a broad surface to install the fixtures. The anticipated implant site has been radiographically predetermined (Fig. 16-5A–D). Its position is then located on the patient either by measuring from an existing tooth or from another landmark that can be identified both on the films and on the patient or by using a stent with markers (Fig. 16-5B). Refer to the discussion of radiographic and surgical stents.

After the site has been identified on the patient, a series of graduated drill bits produce a hole in the bone. The hole is progressively widened to the appropriate size. A countersink widens the drill hole's entrance to accommodate the fixture head. The hole is then threaded with a titanium tap bur to accommodate the threaded fixture. Both drilling and threading are done at extremely low revolutions per minute (RPM), with copious irrigation to prevent heating and destruction of osteoblasts because osseointegration can only occur with viable cells. The top of the fixture has a threaded hole (Fig. 16-5G) to accommodate the abutment screw that is inserted during the second stage of the procedure. To prevent soft tissue and bone from growing into the hole while the patient is healing, a cover screw is used (Fig. 16-5E). The implant and cover screw are flush with the surface of the bone. To raise the height of the implant above the gingival surface, an abutment is later attached.

After the fixtures are placed, the tissue flap is sutured closed and the implants are allowed to heal for approximately 4 months in the mandible and 6 months in the maxilla (Fig. 16-5F). This promotes the process of osseointegration, thus forming a strong bond between the bone and the implant. Approximately 1 week after the initial surgery, the skin sutures are removed and the patient is fitted with an interim prosthesis, which typically is the one used before surgery. Because of the fixture, minor modifications of the old prosthesis may be necessary.



VIEW IMAGE

FIGURE 16-4 Illustration demonstrating the components of an implant (**A**) and two root form implants supporting a three-tooth prosthesis (**B**). For illustrative purposes, the black portion running through the prosthesis (*arrow*) represents the metal framework within the prosthesis. Prosthesis screw (*Ps*), abutment screw (*As*), abutment (*A*), and fixture (*F*).

Abutment Connection

The second stage of the procedure tends to be less traumatic for the patient and is typically carried out with only local infiltration of lidocaine. A pointed probe is used to locate the cover screws; after they are located, an incision is made to expose and remove them. Alternatively, a circular soft-tissue punch can be used to excise the tissue above the cover screw. The abutment is then attached to the fixture using the abutment screw. The top of the abutment screw has a screw hole that permits the prosthesis to be screwed into the fixture (Figs. 16-4 and 16-5H). Finally, a surgical pack is applied and retained for a short period by a healing cap.

Prosthodontic Procedure

To make the prosthesis, an impression of the jaw with the abutments in place is made, using plaster or hydrocoloid. From this impression a cast of the mandible or maxilla is obtained. From this cast the prosthesis is made, aligning properly with the screw holes and properly aligning the prosthetic teeth with the occlusal plane. After the prosthesis is manufactured, it is fixed to the abutments with screws that typically come out the central fossa of the prosthetic teeth. A white compound is used to cover the screw holes (Fig. 16-5I).

RADIOLOGY FOR ORAL IMPLANTS

To perform the implant procedure, the oral surgeon and dentist need to know the precise height, width, and contour of the alveolar process, as well as its relationship to the maxillary sinus and mandibular canal. Injury to the neurovascular bundle within the mandibular canal results in paresthesia or hypesthesia of the face, whereas perforation into the maxillary sinus increases the likelihood of implant failure and creates the potential for an oroantral fistula and antral infection. The precise dimensions of the alveolar process are important to determine preoperatively because atrophy of the alveolar ridge, which occurs in edentulous patients, may preclude the use of implants.

Before the development of CT dental reformatting programs, attempts were made to obtain this information with panoramic, intraoral, and cephalometric films. However, the panoramic film produced up to 25% distortion, making accurate measurements almost impossible. In addition, the width (thickness) of the alveolar process could not be determined by any of these techniques. Therefore the surgeon had to rely primarily on clinical assessment to determine if the alveolar process was thick enough to accommodate an implant. Unfortunately, it was common to find during surgery that there was insufficient bone for the implants. As a result, radiologists and dentists began to evaluate the efficacy of using CT to assess these patients.[10, 11] Axial and coronal images were only marginally helpful because of the streak degradation artifacts created by any dental restorations. However, reformatted images using thin-slice axial CT were found to be extremely useful because the streak artifact could be avoided, the anatomy could be displayed in multiple planes, the width of the alveolar process could be accurately assessed, and accurate, reproducible millimeter measurements could be made.

Reformatting software programs, which display multiple panoramic and cross-sectional images, soon became available (Figs. 15-2 and 15-3; Chapter 15).[12–15] The particular program used in this chapter is DentaScan. Although these programs were initially developed to assess implant patients, they have also gained popularity for evaluating all lesions of the jaw (Fig. 16-6).[16–19]

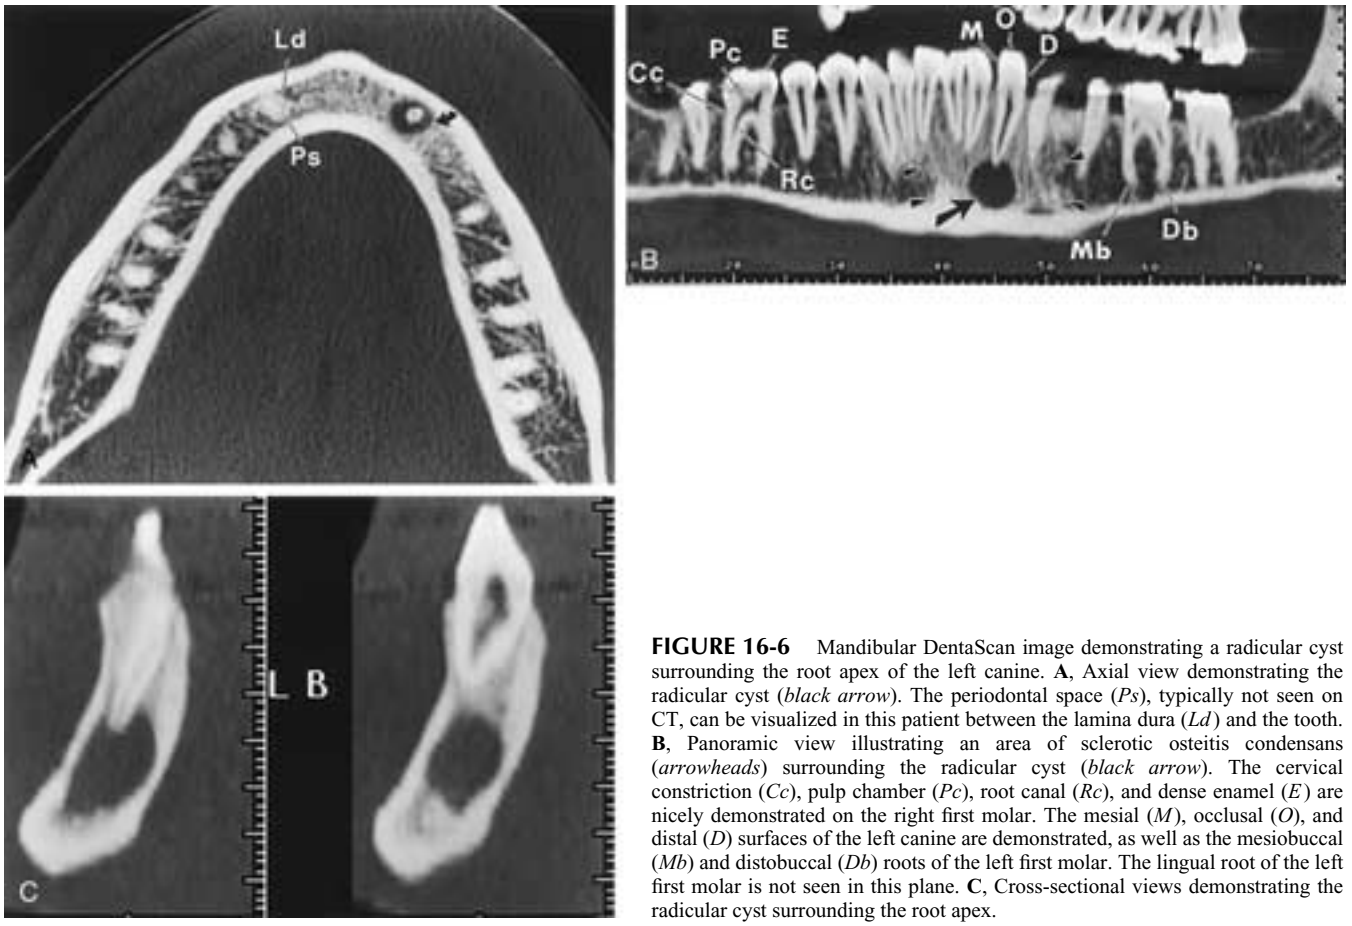

FIGURE 16-6 Mandibular DentaScan image demonstrating a radicular cyst surrounding the root apex of the left canine. **A**, Axial view demonstrating the radicular cyst (*black arrow*). The periodontal space (*Ps*), typically not seen on CT, can be visualized in this patient between the lamina dura (*Ld*) and the tooth. **B**, Panoramic view illustrating an area of sclerotic osteitis condensans (*arrowheads*) surrounding the radicular cyst (*black arrow*). The cervical constriction (*Cc*), pulp chamber (*Pc*), root canal (*Rc*), and dense enamel (*E*) are nicely demonstrated on the right first molar. The mesial (*M*), occlusal (*O*), and distal (*D*) surfaces of the left canine are demonstrated, as well as the mesiobuccal (*Mb*) and distobuccal (*Db*) roots of the left first molar. The lingual root of the left first molar is not seen in this plane. **C**, Cross-sectional views demonstrating the radicular cyst surrounding the root apex.

FIGURE 16-7 Illustration demonstrating a periodontal pocket and its repair. **A**, Bacterial overgrowth has attacked the periodontal ligament (*curved arrow*) and resorbed bone (*straight arrow*), creating this periodontal pocket. **B**, The periodontal pocket in **A** has now been packed with freeze-dried bone (*curved arrow*) and covered with a Gortex graft (*straight arrow*) to prevent ingrowth of soft tissue while the bone graft heals. The Gortex will be removed in approximately 6 weeks.

RELATED PATHOLOGY

Most patients being scanned for dental implants have considerable oral pathology, often related to the inflammatory process that likely caused their edentulism. The inflammatory disease, which often starts as gingivitis (inflammation of the gums), can be divided into periodontal and endodontal disease. Periodontal disease refers to infection of the periodontal ligament along the sides of the root and the adjacent surrounding bone. Endodontal disease refers to infection and resorption of bone at the root apex.

Periodontal Disease

Periodontal disease starts with gingivitis and the accumulation of bacteria-laden plaque around the teeth. This may harden into tartar or calculus, a tough, gritty material that is difficult to remove. The presence of this bacterial overgrowth produces inflammation of the gums, which presents clinically as swelling with frequent bleeding secondary to hyperemia from inflammation. If the infection is allowed to persist, the fibers that attach the gingiva to the tooth become involved, allowing bacteria to access the periodontal ligament (periodontitis). Once the periodontal ligament becomes involved, a periodontal pocket forms in which plaque accumulates adjacent to the root (Fig. 16-7A).

Routine dental hygiene at home does not adequately cleanse these infected regions, and the disease progresses. Eventually the periodontal ligament is destroyed, and the adjacent bone surrounding the root is resorbed.[20] Radiographically, periodontal disease is recognized by the associated bone loss that occurs. On CT, this bone loss appears as a radiolucency surrounding the root of the tooth (Fig. 16-8). The periodontal ligament, which appears as a radiolucency surrounding the root on radiographs (Fig. 16-9), is usually not resolved on CT because it is too thin. Therefore, radiolucency along the root of the tooth on CT usually implies periodontal disease. Because the resolution of radiographs exceeds that of CT, visualization of the periodontal ligament as a thin lucency between the root and lamina dura (surrounding cortical bone) (Fig. 16-9) is routinely seen. Widening of this periodontal space on radiographs implies periodontal disease (Fig. 15-10).

Endodontal Disease

Another frequently encountered condition in this patient population is an inflammatory cyst surrounding the root

VIEW IMAGE

FIGURE 16-8 Panoramic CT scan of mandible demonstrating periodontal disease. The radiolucency surrounding the root of the left first molar (*arrowheads*) is due to bone resorption from periodontitis. The periapical lucency around the root apex of the right canine (*long arrows*) is a radicular cyst secondary to a periapical abscess. Note the metal post in the pulp chamber secondary to a prior root canal procedure (*solid curved arrow*), and compare this with the normal radiolucent pulp chamber of the left first premolar (*open curved arrow*). A zone of relatively dense sclerotic bone (osteitis condensans) is identified surrounding both areas of disease. (From Abrahams JJ. The role of diagnostic imaging in dental implantology. Radiol Clin North Am 1993;31(1):163–180.)

apex called a radicular cyst.[21] Bacteria gains access to the pulp chamber through dental caries and travels down the root canal to the root apex, where either an acute abscess or a more chronic granuloma forms. Bone loss develops around the root apex, and this appears as a periapical radiolucency on CT (Fig. 16-6). When bacteria enters the pulp chamber through dental caries, it causes pulpitis with inflammation and edema. Because the tooth cannot expand, pressure builds within the pulp chamber and the diminished blood flow causes the tooth to die. Radicular cysts are therefore associated with nonvital teeth. The treatment is to drill through the pulp chamber and drain the abscess (root canal procedure). After this drainage is accomplished, the root canal is filled with a radiopaque material that also plugs the apical foramen. This is readily seen on CT as a radiodensity, rather than a radiolucency, in the region of the pulp chamber and root canal (Fig. 16-8, *curved arrow*).

Osteitis Condensans

The chronic inflammatory changes of periodontal and endodontal disease can also cause reactive sclerosis in the adjacent bone, termed osteitis condensans. Radiographically, this appears as a relatively dense zone of bone surrounding an area of periodontal or endodontal disease (Fig. 16-8).[22] This condition is relatively benign, and treatment is directed at eradicating the underlying periodontal and endodontal disease.

Maxillary Sinus Inflammation from Dental Disease

The close proximity of the root apexes to the maxillary sinus makes periodontal and endodontal disease potential sources of infection to cause maxillary sinus disease. It is not uncommon to find mounds of inflammatory tissue within the sinus adjacent to the root apices of diseased teeth. These mounds frequently are misdiagnosed as mucous retention cysts or polyps on axial CT scans[23] (Fig. 16-10).

An oroantral fistula, which is an abnormal communication between the maxillary sinus and oral cavity, typically causes fluid and inflammatory changes in the maxillary sinus. These fistulas are often caused by tooth extractions but can also be caused by infection, trauma, tumors, etc.[24] Radiographically, the oroantral fistula presents as unilateral sinusitis with a bony defect in the floor of the maxillary sinus. This is best seen using dental CT reformatting programs (Fig. 16-11).

Atrophy and Augmentation Procedures

Periodontal and endodontal disease eventually lead to edentulism. The resorption of bone, however, continues even after the teeth are lost. This is because the normal vertical stress applied to the bone from the teeth is no longer present and disuse atrophy occurs. It is believed that the use of dental implants retards this atrophic process. The disuse atrophy affects both the height of the alveolar process (Fig. 16-12A) and the width (Fig. 16-12B). When it is severe, the mandibular canal, which is normally covered by a considerable amount of bone, may lie just under the gingival surface.

Several augmentation procedures are now available for patients who have severe atrophy and have insufficient bone for implants. In the sinus lift procedure, the surgeon elevates

FIGURE 16-9 Periapical radiograph of mandibular central incisors depicts mild loss of alveolar bone from periodontal disease. Alveolar crest (*arrowhead*) is eroded and is now located below the cemento-enamel junction (*white arrow*). Concurrent minimal widening of the periodontal ligament space (*black arrows*) is noted.

FIGURE 16-12 Cross-sectional views of the mandible in two different patients demonstrating bone resorption and atrophy. **A**, Bone loss and atrophy of the height of the mandible in this patient cause the mandibular canal (*arrow*) to sit immediately under the gingival surface. The dotted line demonstrates how the bone contour might have appeared before atrophy. The patient has insufficient bone for implants. (From Abrahams JJ. The role of diagnostic imaging in dental implantology. Radiol Clin North Am 1993;31(1):163–180.) **B**, The width of the mandible in this patient has been considerably diminished due to atrophy. The dotted line again demonstrates how the bone might have appeared before atrophy. (From Abrahams JJ. CT assessment of dental implant planning. Oral Maxillofac Surg Clin North Am 1992;4:1–18.)

the periosteum in the floor of the maxillary sinus and packs a freeze-dried bone graft between the elevated periosteum and the bony floor. After this heals, it will increase the height of the alveolar bone available in the maxilla. In both the mandible and maxilla, various bone grafts alone, often from iliac crest, have been used to increase the height and width of the alveolar process. These grafts may be supplemented with freeze-dried bone.

Finally, if the implant is placed and either the buccal or lingual surface is exposed and uncovered by bone, a procedure known as guided tissue regeneration, which utilizes Gortex as a physical barrier, can be performed to regenerate the bone adjacent to the implant in the following manner. Bone graft is first packed around the exposed surface of the implant, and then a piece of Gortex fabric is placed between the bone graft and soft tissues. The Gortex acts as a barrier, preventing the soft tissues from growing into the bone graft, thus allowing time for the graft to take. Typically the Gortex remains in place for about 6 weeks and is then removed. This procedure can also be used when placing an implant in a fresh extraction socket and for filling a periodontal pocket with bone graft, as illustrated in Figure 16-7B.

Jaw: Cysts, Tumors, and Nontumorous Lesions

Alfred L. Weber, Takashi Kaneda, Steven J. Scrivani, and Shahid Aziz

SECTION ONE: PATHOLOGIC STATES
INTRODUCTION
CYSTS
- Definition and Classification
- Odontogenic Cysts
  - Periapical (Radicular) Cyst
  - Dentigerous (Follicular) Cyst
  - Odontogenic Keratocyst
    - *Basal Cell Nevus Syndrome (Gorlin's or Gorlin-Goltz Syndrome)*
  - Calcifying Odontogenic Cyst (Gorlin Cyst)
  - Other Odontogenic Cysts
- Nonodontogenic Cysts and Pseudocysts
  - Incisive Canal Cyst (Nasopalatine Duct Cyst)
  - Solitary, Simple, or Hemorrhagic Bone Cyst (Traumatic Bone Cyst)
  - Aneurysmal Bone Cyst
  - Static Bone Cavity (Stafne Cyst)
  - Medullary Pseudocyst

BENIGN ODONTOGENIC TUMORS AND RELATED TUMOR-LIKE CONDITIONS
- Ameloblastoma (Epithelial Origin)
- Calcifying Epithelial Odontogenic Tumor (Pindborg Tumor)
- Odontoma (Mixed Tumor)
  - Complex Odontoma
  - Compound Odontoma
  - Ameloblastic Fibroodontoma
  - Adenomatoid Odontogenic Tumor
  - Odontogenic Myxoma

CEMENTAL LESIONS
- Periapical Cemental Dysplasia and Florid Cemental Dysplasia (Florid Cementoosseous Dysplasia)
- Benign Cementoblastoma

BENIGN NONODONTOGENIC TUMORS
- Exostosis
- Osteoma
- Osteochondroma
- Chondroma
- Synovial Chondromatosis
- Giant Cell Lesions

LANGERHANS HISTIOCYTOSIS (HISTIOCYTOSIS X)
- Letterer-Siwe Disease

Dentin Dysplasias
DENTAL MANIFESTATION OF METABOLIC AND SYSTEMIC CONDITIONS

SECTION ONE

PATHOLOGIC STATES

INTRODUCTION

Lesions developing within the jaws can arise from the dental elements, bone, nerves, or blood vessels. Classifications of these jaw lesions have varied considerably, with no universally accepted terminology. Some of these classifications have emphasized the presumed cell of origin of various tumors, while the cysts have been classified as being either developmental or inflammatory in etiology. However, as the theories of derivation evolve, classifications change. The World Health Organization (WHO) classification published in 1992 is widely accepted (Table 17-1).[1] In this classification, the tumors are separated into benign and malignant types and further subdivided based on the odontogenic tissue types involved in the generation of the lesion. This section does not precisely follow the WHO classification, and not all of the rare tumors mentioned in it are included in this chapter. Several excellent and more complete reference works are cited in the References (also see Chapters 6, 15, and 27 for further discussions of these lesions).[2, 3]

It should be noted that the groupings in this section are not precise. For instance, the various cemental lesions are grouped together under benign odontogenic tumors and tumor-like conditions. Clearly, many of these lesions could have just as easily been included in the fibroosseous category. It is hoped that the organization of this chapter will be helpful to those who are less familiar with maxillofacial lesions and allow this complex topic to be more readily understood. The cystic lesions are discussed first, followed by true tumors and tumor-like conditions. Finally, infections of the jaw are discussed.

CYSTS

Definition and Classification

A cyst is characterized pathologically as an epithelium-lined cavity that contains fluid or semisolid material.[4] In most cases, microscopic examination of the lining tissue, as well as the clinical and radiographic findings, is necessary to achieve a diagnosis.

Cysts frequently occur in the jaw and appear radiographically as either unilocular or multilocular lucent areas of varying size and definition. Cysts of the mandible can come to clinical attention by remodeling bone and thus weakening the mandible, causing functional disturbances, or by the effects of secondary cyst infection. Delayed tooth eruption and displacement and resorption of tooth roots are often seen on imaging, and the cyst's relationship to a tooth is an important differential diagnostic feature. On the basis of the cell of origin, cysts have been subdivided into odontogenic and nonodontogenic types.

Odontogenic cysts arise from tooth derivatives.[5] Frequently, odontogenic cysts are divided into inflammatory and developmental types, with the developmental variety not being directly associated with inflammation. In some lesions the pathogenesis is unclear. Histologic analysis of the epithelial layers, the presence of cyst calcification, and the clinicial findings allow further subdivision of these cysts. The term *residual cyst* is frequently applied to any cyst (but specifically to a periodontal apical cyst) that remains or develops after surgical removal of a tooth.

Most odontogenic cysts are developmental in origin.[1] The fissural variety, as the name implies, arise along lines of fusion of the various bones and embryonic processes, and they are classified according to their anatomic location. Several cysts previously classified as fissural cysts have been moved into other categories, as their relationship to embryonic fusion or, alternatively, their worthiness of a separate category has been questioned. Developmental cysts

Table 17-1
WHO HISTOLOGIC CLASSIFICATION OF JAW TUMORS AND CYSTS
The classification is provided for completeness. Classifications of jaw lesions vary, and this chapter does not follow this classification exactly.

Histologic Classification of Odontogenic Tumors

Neoplasms and Other* Tumors Related to the Odontogenic Apparatus

Benign

*Odontogenic epithelium without odontogenic ectomesenchyme**
- Ameloblastoma
- Squamous odontogenic tumor
- Calcifying epithelial odontogenic tumor (Pindborg tumor)
- Clear cell odontogenic tumor

*Odontogenic epithelium with odontogenic ectomesenchyme, with or without dental hard-tissue formation**
- Ameloblastic fibroma
- Ameloblastic fibrodentinoma (dentinoma) and ameloblastic fibroodontoma
- Odontoameloblastoma
- Adenomatoid odontogenic tumor
- Calcifying odontogenic cyst
- Complex odontoma
- Compound odontoma

*Odontogenic ectomesenchyme with or without included odontogenic epithelium**

- Apical and lateral
- Residual
- Paradental (inflammatory collateral, mandibular infected buccal) cyst

*The enamel organ derives from the odontogenic epithelium developing from the ectoderm of the oral cavity. The dental papilla and follicle are considered ectomesenchymal, derived partly from the neural crest. Lesions that contain odontogenic ectomesenchyme, as well as the odontogenic epithelium, have the capability of producing dentin and enamel. Those without ectomesenchyme cannot. Some lesions arise primarily from the mesenchyme and appear to incidentally include ''odontogenic epithelium,'' but the odontogenic epithelium does not play a key role in producing the lesion.

include other cyst types derived from embryologic structures, such as dermoid cysts, and cysts arising from other causes, such as solitary bone cysts and aneurysmal bone cysts. Stafne's cyst is not a cyst at all but rather a variation in the development of the cortex of the bone.

Odontogenic Cysts

Periapical (Radicular) Cyst

Periapical (radicular) cyst is by far the most common odontogenic cyst.[1] It may form at any time during life, although the peak incidence is between 30 and 50 years of age. There is no sex predilection. This cyst is associated with carious teeth. Caries lead to infection of the pulp cavity and eventually pulp necrosis. Infection passes out of the apex of the root, resulting in apical periodontitis leading to an acute abscess or a more chronic granuloma. From these stages, the disease can quiesce and form the periapical (radicular) cyst. Most periapical cysts are discovered incidentally on radiography, but expansion of the cyst may cause a clinically noticeable displacement of teeth, and swelling and pain may occur when the cyst enlarges or becomes secondarily infected.

Radiographically, a radicular cyst is a well-circumscribed radiolucency arising from the apex of the tooth and bounded by a thin rim of cortical bone (Figs. 17-1 and 17-2). Large lesions may expand the cortical plates.[6] A radicular cyst can displace tooth structures and may cause slight root resorption. If the cyst occurs in the maxilla, extension into the maxillary sinus may be observed (Fig. 17-3). Radiographically, radicular cysts cannot be differentiated from periapical granulomas, which usually are less than 1.6 cm in diameter. On MR imaging, the lesions usually have high signal intensity on T2-weighted images and variable signal

intensity on T1-weighted images. On contrast-enhanced MR imaging, the cysts wall is usually thick and there is strong enhancement, probably representing inflammation.

Dentigerous (Follicular) Cyst

The dentigerous cyst is the second most common odontogenic cyst after the inflammatory periapical cyst . The dentigerous cyst forms around the crown of an unerupted tooth (Figs. 17-4 and 17-5). This tooth will never erupt. Fluid collects between layers of epithelium or between the epithelium and the enamel. Most dentigerous cysts become evident during the third and fourth decades of life, and most (75%) are located in the mandible. In the usual case, the tooth crown projects into the lumen of the cystic cavity. The wall of the cyst tends to converge to the cementoenamel junction. With continued cyst growth, only a limited portion of the tooth may be attached to the cyst lining.

Dentigerous cysts vary greatly in size, ranging from less than 2 cm in diameter to those that cause massive expansion of the jaw. They may cause displacement of teeth, but apical resorption of tooth structures is uncommon. Fractures and superimposed infection may develop in the cyst. Dentigerous cysts do not demonstrate an extracystic soft-tissue mass, as seen in ameloblastomas, but ameloblastomas, mucoepidermoid tumors, and carcinomas may develop in the wall of the cyst.

On imaging, a mandibular dentigerous cyst appears as a well-circumscribed unilocular area of osteolysis that incorporates the crown of a tooth. The adjacent teeth are displaced and may be partly eroded. Dentigerous cysts in the maxilla often extend into the antrum, displacing and remodeling the bony sinus wall (Fig. 17-6). Large cysts may project into the nasal cavity or infratemporal fossa and may elevate the floor of the orbit. In the mandible, buccal or lingual cortical expansion and thinning are noted. On MR imaging, the contents of the cyst show high signal intensity on T2-weighted images and low to intermediate signal intensity on T1-weighted images. The tooth itself is an area of signal void (Fig. 17-7). The lining of the cyst is thin and regular in thickness and may show slight enhancement after contrast injection.

Odontogenic Keratocyst

Odontogenic keratocysts (OKC) account for 3% to 11% of all jaw cysts and occur twice as often in the mandible as in the maxilla.[7–9] These cysts are found in patients of all ages, but the peak incidence is in the second and third decades of life. This cyst has been classified as a separate type of bone cyst because of its aggressive biologic behavior and histologic structure. Histologically, the cyst is lined by a stratified keratinizing squamous epithelium. The epithelium is characteristically thin, six to eight cell layers, and the keratinization is usually of the parakeratin type. Parakeratin has nuclei in the layer of keratin that borders the lining of the cyst. There is no keratogranular layer in the wall. Parakeratinization is a more disordered type of keratin formation than orthokeratinization. With the formation of orthokeratin, there is a granular layer and nuclei are not sloughed into the keratin. Orthokeratinizing epithelium is considered to reflect the normal keratinization process, as seen in the epithelial layer of the skin.

In the keratocyst, the interface between the epithelium and the connective tissue is flat, without rete ridge formation. The basal layer is prominent, with palisading cells containing darkly staining and enlarged nuclei. Daughter (satellite) cysts or microcysts may be observed microscopically. The recurrence rate has been variously reported as being between 20% and 60%. This high recurrence rate is thought to be the result of the specific abnormal biology of these cysts. Various hypotheses have

Copyright © 2003, Mosby, Inc. All rights reserved.

been proposed in an attempt to explain this rate and solve this problem.[10, 11]

The diagnosis depends on the cyst's microscopic features and is independent of its location and radiographic appearance. This cyst is a radiolucent lesion that may be multiloculated, with a smooth or scalloped border (Fig. 17-8). These cysts are characteristically located in the body and ramus of the mandible and may occur in conjunction with an impacted tooth (Figs. 17-9 and 17-10). The lesion usually grows along the length of the mandible and does not usually resorb teeth roots. CT shows a well-defined unilocular or multilocular cystic radiolucency with a bony sclerotic margin and bulging of the bony cortex (Fig. 17-11). Sometimes the content of the cyst shows higher density than water due to keratinized material.[12] The MR imaging appearance is variable but typically shows a cystic pattern with a regularly thin wall, heterogeneous intensity of fluid contents, and weak contrast enhancement of the cyst wall (Fig. 17-12).[13] The signal intensity on T2-weighted sequences is usually high but is variable, depending on the protein concentration of the contents.

One variant of the OKC has a true orthokeratinizing epithelial lining (see above). Although truly a keratocyst, the lesion exhibits significantly less aggressive behavior than the parakeratinizing variant. Some prefer to categorize these lesions separately as an orthokeratinizing keratocyst rather

Note that there is also expansion, with thinning of the anterior wall of the ascending ramus.

than a variant of the typical keratocyst. At imaging, the two lesions cannot be distinguished unless studies over time show the aggressive growth more typical of the parakeratinizing OKC.

The surgical management of OKC demands special attention because of the aggressive biologic behavior of these benign lesions.[14] Surgical treatment over the years has included decompression and marsupialization, enucleation and curettage, and local and en bloc resection and reconstruction. Various adjuvant methods of treatment have been used to decrease the potential for recurrence or to deal with a recurrence. These include extraction of teeth in continuity with the cyst, excision of overlying mucosa, and treatment of the surrounding bone with peripheral ostectomy, chemical cautery, or cryosurgery. Many of these lesions, especially recurrences, are treated with some combination of these surgical techniques. Regardless of the management strategy employed or the surgical outcome, these patients must be closely followed for many years.

The term *primordial cyst* is now usually considered to be synonymous with OKC. However, some consider the term to be more appropriately applied only to the rare cysts that contain nonkeratinized squamous epithelium rather than the typical keratinized lining typical of the keratocyst.[2] Primordial cysts are considered to arise from a degenerated enamel organ and are therefore found in place of a missing tooth (Fig. 17-13).

Basal Cell Nevus Syndrome (Gorlin's or Gorlin-Goltz Syndrome)

Basal cell nevus syndrome (nevoid basal cell carcinoma syndrome) is a genetic disorder inherited as an autosomal dominant trait with variable penetrance and expressivity.[15, 16] The syndrome becomes apparent between 5 and 10 years of age. There is no sex predilection, and many patients with this syndrome have slight mental retardation. The syndrome comprises a number of features that are classically grouped into five categories: cutaneous, skeletal, ophthalmologic, neurologic, and sexual. Among the most common features are multiple cysts of the jaw, multiple basal cell carcinomas, skeletal abnormalities, and ectopic calcifications. At least two of these findings must be present to establish a diagnosis.

The multiple jaw cysts develop early in childhood[17]; they may be either unilocular or multilocular and often prove to be keratocysts varying in size from 1 mm to several centimeters (Fig. 17-14). Many investigators have suggested that the OKCs in basal cell nevus syndrome are histologically and biologically different from the solitary OKCs not associated with this syndrome. Those associated with the syndome occur earlier and are more likely to recur after excision. However, this concept is not universally agreed upon. Some investigators believe that the cysts associated with this syndrome are just larger, multilocular, and tend to have more frequent satellite microcysts that may account for their clinical behavior. Nevoid basal cell carcinomas tend to appear later than cysts, usually before 30 years of age, and are found especially on the face, trunk, neck, and arms. The most common skeletal abnormalities are bifid ribs, synostosis of ribs, kyphoscoliosis, vertebral fusion, mild ocular hypertelorism, prognathism, polydactyly, and frontal and temporoparietal bossing. The ectopic calcifications occur most frequently in the falx cerebri and other areas of the dura.

Calcifying Odontogenic Cyst (Gorlin Cyst)

A calcifying odontogenic cyst is a rare developmental odontogenic lesion having features of both a cyst and a solid neoplasm. It was defined as a distinct entity by Gorlin et al. in 1962[18] and is listed by the WHO as an odontogenic epithelial cyst having odontogenic ectomesenchyme, with or without dental hard tissue formation. In the most recent WHO classification, the calcifying odontogenic cyst is also classified as a tumor.[1] The terms *calcifying odontogenic cyst* and *odontogenic ghost cell tumor* are used. The ghost cell tumor designation results from a characteristic cell found in the wall of the cyst. Ghost cells have eosinophilic cytoplasm and no nuclei. These cells can calcify.

The lesion occurs at many ages but is most commonly found in the second or third decade of life, with an almost equal sex distribution and a similar incidence in the mandible and the maxilla. Those in the maxilla are usually anterior. Radiographically, the cyst may present as a unilocular or multilocular radiolucency with discrete, well-defined margins containing scattered calcifications of irregular size (Figs. 17-15 and 17-16).[19–22] Such opacities may produce a ''salt-and-pepper-like'' appearance. Displacement of teeth or root resorption is occasionally seen. The lesion is sometimes associated with unerupted teeth. If it is seen along with a complex odontoma, those opaque components may be seen to merge (Fig. 17-15). The radiologic appearance may be similar to that of adenomatoid odontogenic tumor, ameloblastic fibro-odontoma, or calcifying epithelial odontogenic tumor (Pinborg).

Other Odontogenic Cysts

As stated, there is overlap in the descriptions of several entities. Several terms or named cysts deserve mention for completeness.[2, 3]

The lateral periodontal cyst is considered to be a developmental cyst arising from epithelial remnants in the periodontal ligament along the lateral aspect of the tooth root. It is not inflammatory and should be distinguished from the occasional occurrence of an inflammatory lateral radicular cyst that can occur here as well. The botryoid odontogenic cyst may simply be a multicystic variant of the lateral periodontal cyst.

Several cysts are thought by some to be most likely of an inflammatory origin, arising from epithelial rests in the periodontal space. The lateral radicular cyst has been mentioned as analogous to the periapical radicular cyst but occurring along the lateral aspect of the root. The term *paradental cyst* also describes an inflammatory cyst along the sides of the root. Originally described along the lateral aspect of the third molar, the term has been applied to other teeth as well.

OKC can also be heterogeneous. **F**, Axial T1 postgadolinium image shows a thin, regular enhancing margin. Note that a thin soft-tissue enhancing margin (*arrow*) borders and ''covers'' the tooth. **G**, Coronal T1-weighted image. **H**, Coronal T1-weighted image after gadolinium enhancement shows the thin, regular enhancing wall (*arrows*) of the keratocyst.

The buccal bifurcation cyst arises from the periodontium at the bifurcation of the lateral (buccal) roots of the mandibular molars, usually the first. The roots tend to tip lingually. Although it is considered most likely related to inflammation, inflammation is not always present. The term *paradental cyst* (see above) has been applied to this lesion as well.[3]

Nonodontogenic Cysts and Pseudocysts

Incisive Canal Cyst (Nasopalatine Duct Cyst)

A nasopalatine duct cyst (incisive canal cyst) is a nonodontogenic developmental cyst or fissural cyst arising in the nasopalatine duct near the anterior palatine papilla.[23, 24] It is the most common nonodontogenic cyst. The cysts probably arise from epithelial remnants in the incisive canal. They can occur at any age but are most frequently found in the fourth and sixth decades of life, with no sex predilection. These cysts are usually asymptomatic, but some patients note swelling in the palate, especially when the cyst is primarily in the incisive papilla. Alternatively, the anterior maxilla can be remodeled forward, elevating the columella of the nose. Occasionally, patients notice a discharge of mucoid material and a salty taste through what are thought to be remnants of embryonic ductal structures on the palate.

Many of these cysts are small and are found on routine plain film radiographic surveys. It may be difficult on imaging to differentiate between an enlarged incisive fossa and an incisive canal cyst. The incisive canal cyst is always located at or close to the midline and usually is round or

Copyright © 2003, Mosby, Inc. All rights reserved.

ovoid, although it may be heart-shaped (Fig. 17-17). A condensed rim of cortical bone is often seen along the periphery, and the lesion may displace the roots of the central incisor teeth.

The nasolabial or nasoalveolar cyst is considered most likely a fissural cyst arising adjacent to bone at the root apex of the incisors just beneath the lip. It may scallop the bone along the anterior cortex of the maxilla. This lesion is also discussed in Chapter 6.

Several terms are no longer used. The term *globulomaxillary cyst* referred to a cyst located between the lateral incisor and the canine tooth, at the site thought to correspond to a developmental fusion line between the lateral nasal and maxillary processes.[25, 26] Today there is evidence that these cysts do not arise from ''trapped'' epithelium but are probably simply cysts of odontogenic origin (Fig. 17-18). A cyst in this location is now thought to be either a radicular cyst or perhaps a keratocyst.

The median palatal cyst is now frequently grouped with nasopalatine cysts rather than considered a separate entity.

Solitary, Simple, or Hemorrhagic Bone Cyst (Traumatic Bone Cyst)

Solitary, simple, or hemorrhagic bone cysts are seen more frequently in men than in women and are usually found in young people, with 70% occurring in the second decade of life.[27, 28] The etiologic factors are usually obscure. Yet, whether this cyst results from an injury not associated with a fracture that causes an intramedullary hematoma that disintegrates, producing the cyst within the bone, or is perhaps the result of aseptic necrosis or degeneration of an earlier benign tumor, the end result appears to be the same. A hemorrhagic bone cyst is a unilocular cavity that can be partly filled with a clear or sanguineous fluid. The cyst lining

VIEW IMAGE

consists of a loose vascular connective tissue that may have areas of recent or old hemorrhage.[29, 30]

Because these solitary bone cysts often are asymptomatic, most are discovered incidentally during examination of the teeth, and it is believed that some of them regress spontaneously. These lesions are most commonly located in the mandibular marrow space that extends posteriorly from the premolar region. Less often, they may occur in the incisor area of the mandible. Radiographically, these cysts are slightly irregular in shape and size and have poorly defined borders, and the outline of the cyst between the roots of the teeth has a scalloped appearance (Fig. 17-19). Larger cysts may extend into the interdental space. The ramus and body of the mandible may be slightly expanded (Fig. 17-20). The radiographic features are not sufficiently specific to be diagnostic. On MR T1-weighted images, the cyst may show variable signal intensities ranging from low to high according to the age of the hematoma. CT may be helpful to evaluate the contents of the cyst, as a relatively high density is consistent with blood products, but the density can be variable.

These lesions are usually investigated surgically with a single diagnostic and therapeutic procedure. Using a minimally invasive technique, the surgeon can evaluate the lesion and sample tissue. Healing usually takes place with reossification.

Aneurysmal Bone Cyst

These rare lesions are far more common in children than in adults, in females than in males, and in the mandible than in the maxilla or zygoma.[31–34] They usually present with a rapidly growing swelling that can be markedly disfiguring, and there is usually no pain or paresthesia. There can be spontaneous bleeding from around the teeth or from areas of mucosal trauma. Although there is often a history of prior trauma, these cysts can occur without this history, and they may be associated with a preexisting intraosseous pathologic process. Radiographically, these lesions are often multiloculated, with areas of bone destruction (Fig. 17-21). On CT or MR imaging, fluid-fluid levels may be present, a finding strongly suggestive of this entity. Histologically,

they are epithelium-lined, blood-filled cavities with accumulations of immature connective tissue, multinucleated giant cells, osteoid, and inflammatory cells. Numerous approaches have been used to treat these lesions, including interventional radiologic procedures, low-dose radiation therapy, and multiple types of surgical enucleation and resection. More recently, these and other types of giant cell lesions have been treated with calcitonin, interferon, and direct intralesional steroid injections.[35, 36]

Static Bone Cavity (Stafne Cyst)

A Stafne cyst is a pseudocyst. The cortex of the mandible bows inward into the medullary space of the mandible. A

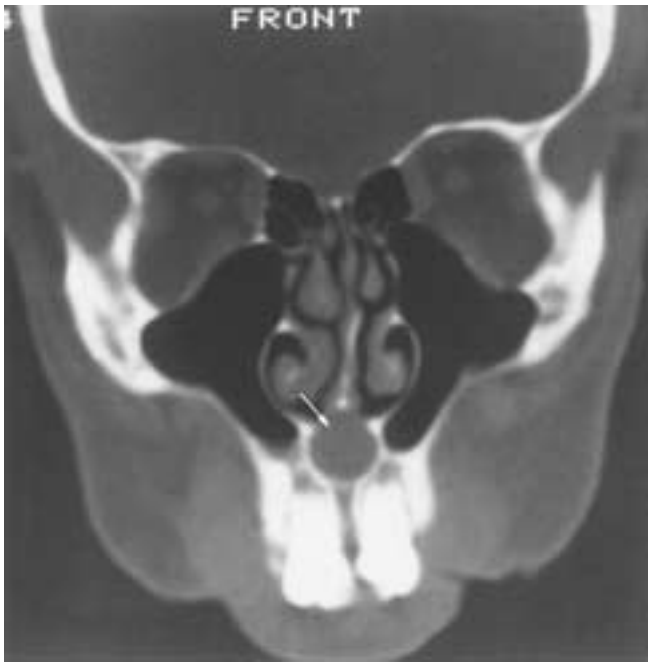

FIGURE 17-17 Nasopalatine cyst. Coronal CT (bone window setting) shows a cyst with bony expansion in the nasopalatine duct between the upper central incisor teeth (*arrow*). There is a slight bulge into the adjacent nasal cavity.

VIEW IMAGE

Stafne cyst appears as an elliptical ovoid or round radiolucency usually located on the medial surface of the posterior mandible, often near the angle of the mandible below the mandibular canal and the mylohyoid line of the mandible (Fig. 17-22). Stafne cysts occur more frequently in men than in women and have been reported in patients from 20 to 70 years of age. Most are discovered by 50 years of age. These asymptomatic lesions are usually detected incidentally on routine radiographs of the mandible. [37] The bone ''defect'' usually contains submandibular salivary gland tissue or fat.[38] The cortex is intact, separating the medullary space of the mandible from the soft tissues in the submandibular space along the medial aspect of the bone (Fig. 17-23). Bilateral lesions have been described.

FIGURE 17-18 ''Globulomaxillary cyst.'' Pantomogram shows a cystic structure (*arrow*) in the right maxilla causing divergence of the roots of the lateral incisor and canine tooth.

VIEW IMAGE

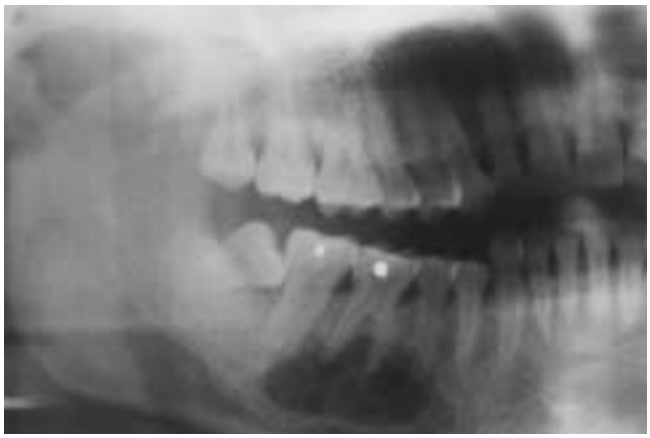

FIGURE 17-19 Hemorrhagic bone cyst in the body of the right mandible. Pantomogram of the mandible shows a sharply defined, oval-shaped cyst around the apices of the molar and premolar teeth of the right mandible.

VIEW IMAGE

Radiographically, the radiolucency has a well-defined border, often with a sclerotic margin, and varies in size from 1 to 2 cm (Figs. 17-22 and 17-23). The cortex follows along the lateral aspect of the abnormality, projecting into the bone. Diagnostic evaluation is usually needed to rule out lesions that are actually located within the bone.

Medullary Pseudocyst

The number of trabeculae crossing the medullary cavity of the mandible is variable. An area with relatively few trabeculae can give the appearance of a lucency mimicking a cyst on a plain film or parorex. Usually there is no sharp or sclerotic margin. In the adult, most of the medullary space is filled with fat, so the diagnosis of pseudocyst is readily made by the characteristic density on CT or signal intensity on MR imaging.

BENIGN ODONTOGENIC TUMORS AND RELATED TUMOR-LIKE CONDITIONS

Odontogenic tumors result from an abnormal proliferation of the cells and tissues involved in odontogenesis.[39, 40] They represent a diverse group of lesions that are classified according to the origin of the various layers of tooth development. Based on the histologic findings, these tumors have been divided into epithelial, mesodermal, and mixed tissue tumors of odontogenic origin.[3] The radiographic appearance of odontogenic tumors varies, and many of them cannot be differentiated from the cysts previously described.

Ameloblastoma (Epithelial Origin)

An ameloblastoma is a benign epithelial odontogenic tumor thought to arise from ameloblasts (enamel-forming cells).[41–43] It is found with about equal frequency in men and women and has a peak incidence in the third and fourth decades of life, with two thirds of cases occurring before 40 years of age. Ameloblastomas account for approximately 18% of odontogenic tumors; 81% are located in the mandible, and the remaining 19% are found in the maxilla. Half of the mandibular lesions are located in the molar regions. An ameloblastoma is a slow-growing, painless mass that may reach a considerable size; swelling is the most common presenting symptom. Ameloblastoma may mani-

fest in a number of histologic patterns, including the follicular, plexiform, acanthomatous, keratinizing, granular cell, basal cell, and clear cell types. In 1984 Eversole et al. described a desmoplastic variant of ameloblastoma.[44] This unusual variant was characterized histologically by an abundant densely collagenous stroma (desmoplasia) with small nests and strands of odontogenic epithelium.[3]

Radiographically, an ameloblastoma is radiolucent and either multilocular or unilocular (Figs. 17-24 and 17-25). The unilocular lesions occur most often in the maxilla (Fig. 17-26). The multilocular form often has been described as having a honeycombed or bubble-like appearance, and the loculi may be oval or spherical and vary in size. Ameloblastomas can vary in size from a small cyst confined to the alveolus to a large cyst that causes extensive destruction of the mandible or maxilla. The tumor has a tendency to break through the cortex of the bone, with subsequent tumor extension into the adjacent soft tissues (Figs. 17-27 and 17-28). There can be bony expansion of variable degree, sometimes with scalloped marginal sclerosis, and there is no periosteal new bone formation. Loss of the lamina dura, erosion of the tooth apex, and displacement of the teeth are also commonly seen. MR imaging findings in ameloblastomas include mixed patterns of solid and cystic components, irregularly thick walls, papillary projections, and marked enhancement of the walls and septa (Fig. 17-29). The demonstration of papillary projections and solid components on contrast-enhanced T1-weighted images is especially helpful in differentiating ameloblastomas from various other cysts (Fig. 17-30).[45] However, the desmoplastic variant of ameloblastoma shows unusual radiographic features such as a mixed radiolucent-radiopaque appearance with poorly defined borders. Because of its appearance, it can be mistakenly diagnosed as a fibroosseous lesion (Fig. 17-31).[46, 47]

The biologic behavior of these lesions has been of great interest and debate. Numerous clinical and histopathologic studies have evaluated the several varieties of ameloblas-

FIGURE 17-24 Ameloblastoma. Oblique view of the mandible shows a large cystic lesion in the body and ramus of the mandible, with attenuation and loss of bone superiorly. The lesion has broken through the upper part of the mandible.

toma in an attempt to relate the clinical picture, histologic pattern, and biologic behavior to provide more appropriate treatment. However, at this time, there does not seem to be any good correlation and the treatment strategies remain predominantly surgical. A variety of approaches have been advocated based on the individual patient. These include curettage and adjuvant treatment of the surrounding soft tissues, wide local excision, and large en bloc excisions with immediate or staged reconstruction. A malignant form of ameloblastoma accounts for 1% of the ameloblastomas. With recurrent tumors and delayed reconstructions, CT, MR imaging, and technetium bone scanning can be helpful in evaluating whether a soft-tissue mass is a recurrence or fibrous healing.

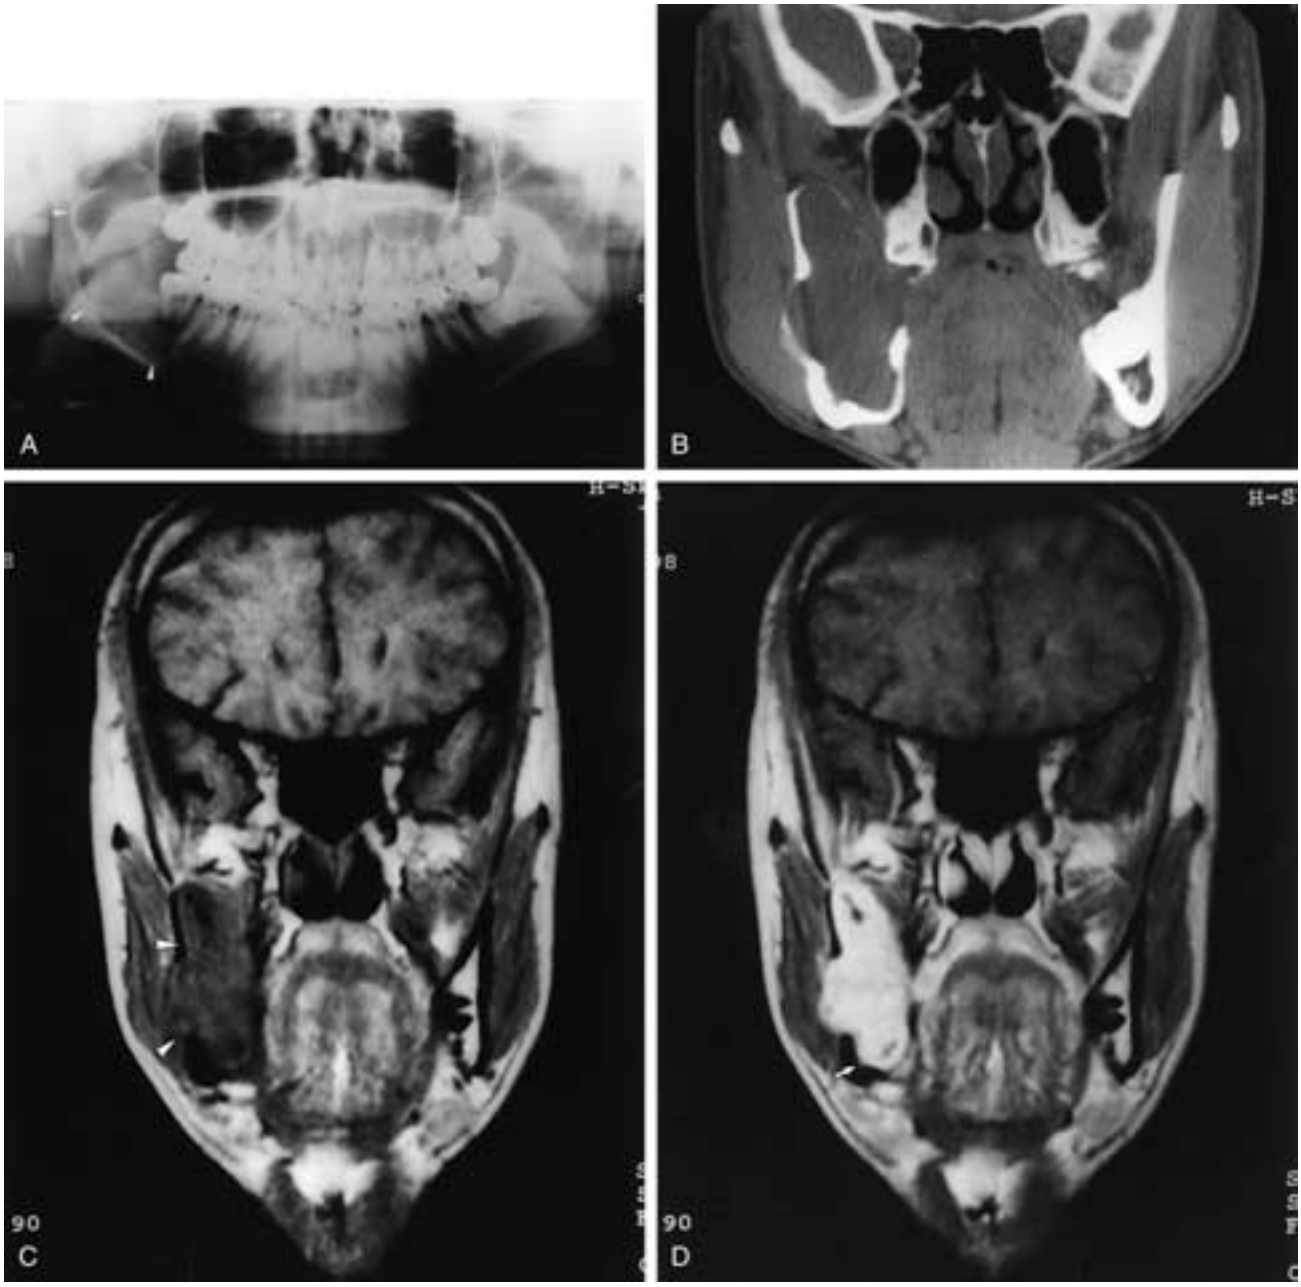

FIGURE 17-25 Multilocular ameloblastoma in a 25-year-old man. **A**, Pantomogram shows a large, multilocular, expansile lesion in the right side of the mandible (*arrowheads*). The mandibular canal is seen under the tumor (*arrowhead*).

Calcifying Epithelial Odontogenic Tumor (Pindborg Tumor)

A calcifying epithelial odontogenic tumor is composed of polyhedral epithelial cells in a fibrous stroma that contains acidophilic homogeneous structures that commonly calcify.[48–50] At first diagnosis the average age of the patient is about 40 years, with an age range of 12 to 78 years. There is no sex predilection. Many of these tumors are located in the premolar-molar area of the mandible, and in half of the cases they are associated with the crown of an impacted tooth.

Radiographically, the lesion usually is a mixed radiolucent and radiopaque mass that may be unilocular but more often is multilocular and honeycombed. It has poorly defined, irregular borders that reflect its aggressive behavior, which is similar to that of the ameloblastoma. Radiopaque densities of varying degree may be located close to the crown of an impacted tooth (Fig. 17-32). Curettage is the preferred treatment, but recurrence or extensive tumor involvement should be treated by resection.

Odontoma (Mixed Tumor)

An odontoma is a benign tumor made up of the various components of teeth (e.g., enamel, dentin, cementum, and pulp). It is also designated as a composite lesion because of the admixture of several types of tissue.[5, 51–54] During its maturation, an odontoma passes through the same stages as a developing tooth, but dentin and enamel are laid down in an abnormal pattern. In the initial stage of development, a radiolucent area develops because of bone resorption by the odontogenic tissues. In the intermediate and late stages, progressive calcification takes place, initially characterized by small, speckled calcific densities that eventually form radiopaque masses surrounded by a lucent ring. These tumors may be discovered in any location of the dental arches and are situated between the roots of teeth.

Both forms of odontoma (complex and compound) are frequently associated with unerupted teeth. It is noteworthy that compound odontomas occur most often in the anterior jaw, whereas complex odontomas tend to occur in the posterior jaw. A developing odontoma without calcification or with few calcifications is difficult to diagnose radiograph-

Copyright © 2003, Mosby, Inc. All rights reserved.

ically and usually cannot be differentiated from other similar-appearing lesions.

Complex Odontoma

Complex odontomas (complex composite odontomas) account for 24% of all odontomas.[52, 53] These lesions are composed of dental tissues arranged in a disorderly pattern and bearing no morphologic similarity to normal or rudimentary teeth (Figs. 17-33 and 17-34). Complex odontomas most commonly occur in patients aged 10 to 25 years, and males and females are affected equally. The lesion usually is asymptomatic and most frequently is located in the premolar and molar regions in the mandible, although it is sometimes found in the maxilla. Most lesions are small, measuring only a few millimeters, but some may reach a considerable size.

Radiographically, these lesions are well-demarcated radiopaque masses, often with radiating structures. Occasionally, the tumor is surrounded by a narrow radiolucent zone, and there usually is a nearby unerupted tooth. The preferred therapeutic treatment is enucleation. Cancellous bone grafting may be appropriate, depending on the size and location of the surgical defect.

Compound Odontoma

Compound odontoma (compound composite odontoma) consists of dental tissues that are similar to a normal tooth, having a more orderly pattern than that seen in complex odontoma.[54] The lesion is composed of many tooth-like structures, with enamel, dentin, cementum, and pulp arranged as in a normal tooth (Figs. 17-35 and 17-36). The

differentiation of teeth varies from case to case, and the number of teeth involved may be surprisingly high.

Most compound odontomas (60%) occur in the second and third decades of life, and there is no sex predilection. The tumor frequently is located in the incisor-canine region of the maxilla. It is usually small but may occasionally displace teeth or interfere with their eruption; the lesion is otherwise asymptomatic. Radiographically, several small, rather well-defined, malformed or rudimentary teeth are demonstrated, surrounded by a radiolucent zone that is caused by a fibrous capsule. The teeth contained in a compound odontoma are dwarfed and usually distorted, with simple roots (Fig. 17-37). Most of these lesions are well encapsulated and easily enucleated, and recurrences are not encountered after enucleation.

Ameloblastic Fibroodontoma

An ameloblastic fibroodontoma is a mixture of ameloblastic tissue and a composite odontoma. It is a rare lesion that can occur at any age but is more prevalent in children than in adults, being rare after the age of 13 years. This tumor is more common in the mandible (premolar-molar

region) than in the maxilla, and it is always associated with developing teeth. Painless swelling or absence or displacement of teeth are the most common signs leading to its diagnosis.

Radiographically, the tumor has a lucent, well-defined margin with a solitary mass or several small radiopaque masses that may resemble miniature teeth (Fig. 17-38). Radiographic differentiation from other odontomas is not possible, and inadequate removal may be followed by a recurrence.

Adenomatoid Odontogenic Tumor

An adenomatoid odontogenic tumor, formerly known as adenoameloblastoma, is a tumor of odontogenic epithelium with duct-like structures and with varying degrees of inductive changes in the connective tissue.[3] It is relatively rare, accounting for approximately 3% of all odontogenic tumors.[55, 56] The tumor is seen more frequently in female patients. It usually occurs in the second decade of life and is present as a slow-growing, painless swelling. The maxilla is involved nearly twice as frequently as the mandible. Radiographically, the tumor is associated with the crown of an embedded tooth mimicking a dentigerous cyst. The radiolucency is well demarcated. Some tumors have a totally radiolucent center; others have punctate calcifications either sprinkled throughout (giving a cloud-like appearance) or in clusters (Fig. 17-39). The tumor can displace or prevent the

Copyright © 2003, Mosby, Inc. All rights reserved.

eruption of teeth, especially the canine. Root resorption is rarely encountered. The radiologic appearance may be similar to that of calcifying odontogenic cyst, ameloblastic fibroodontoma, and calcifying epithelial odontogenic tumor.[57]

Odontogenic Myxoma

An odontogenic myxoma appears to be a true odontogenic tumor, originating from the mesodermal portion of the odontogenic apparatus.[3] This tumor, which is not found in bones outside the jaw, accounts for about 3% to 6% of

odontogenic tumors.[58, 59] It occurs most often in the second and third decades of life, with no sex predilection. The tumor consists of rounded and angular cells lying in an abundant mucoid stroma; the lesion is painless, locally invasive, and slow-growing. If untreated, odontogenic myxomas eventually may cause extensive destruction of bone with marked cortical expansion. The mandible and maxilla are involved with about equal frequency; however, in the mandible, the body and ramus are most commonly affected.

Radiographically, several radiolucent areas of varying size are present, septated by straight or curved bony trabeculae that form triangular, quadrangular, or square-shaped compartments (Figs. 17-40 and 17-41).[60, 61] Unilocular cysts have also been described. The radiographic margins of the tumor may be well or poorly defined, and the lesion may simulate ameloblastoma, central giant cell granuloma, or hemangioma. This tumor is benign but very aggressive and rapidly growing. It shows little encapsulation and often extends through bone, with a propensity to invade local soft tissues. It may appear to expand in thin layers into and through bone, as well as into the adjacent soft tissues.

Because of its histology and behavior, the treatment of choice has become wide en bloc resection rather than simple enucleation.[59] A tumor-free margin must be resected because of the tumor's local invasiveness and its tendency to recur. A recurrence rate of 25% after curettage has been reported.

CEMENTAL LESIONS

Periapical Cemental Dysplasia and Florid Cemental Dysplasia (Florid Cementoosseous Dysplasia)

Periapical cemental dysplasia is a rare lesion that occurs most often in the mandibular region, although in rare cases the lesion may develop in the maxilla.[62–65] It always occurs at the roots of teeth. This lesion is more common in women (average age at diagnosis is 40 years) and among Africans/African Americans. In almost half of the patients, pain is the initial symptom; in other patients, a hard swelling may develop that may cause facial asymmetry.

The initial lesion, which is caused by a proliferation of connective tissue from the periodontal membrane, appears as a well-defined radiolucency.[63] However, it subsequently may be transformed into a radiopaque calcified mass. These lesions can be divided radiographically into three stages: (1) a rather well-defined radiolucency at the apex of a tooth (osteolytic or early stage); (2) a lesion that is partly radiolucent and partly radiopaque, with the dense tissue initially central in the lesion (cementoblastic or mixed stage); and (3) a lesion that is transformed into a mineralized radiopaque mass surrounded by a narrow radiolucent zone (mature stage) (Figs. 17-42 and 17-43). The in-

VIEW IMAGE

volved tooth is normal in color and responds normally to tests of vitality.

Periapical cemental dysplasia does not require treatment unless the lesion becomes infected or other disturbing symptoms occur. The treatment of choice is enucleation, with or without extraction of the involved tooth. No recurrences have been reported.

Florid cemental dysplasia (florid cementoosseous dysplasia) is a diffuse form of periapical cemental dysplasia (Fig. 17-44). Pain has been described, but many patients are asymptomatic. There is no clearly defined distinction between multiple periapical cemental dysplasia lesions and florid cemental dysplasia.

The diagnosis is made with plain films or occasionally with CT. MR imaging is not considered helpful (Fig. 17-45).

Benign Cementoblastoma

Also called a true cementoma, a benign cementoblastoma is a rare neoplasm of functional cementoblasts characterized by the formation of a cementum or cementum-like mass connected with a tooth root.[66, 67] The lesion occurs most

FIGURE 17-35 Compound odontoma. CT scan. **A**, Axial image shows small structures containing both enamel and dentine apparently forming small dental units (*arrow*). **B**, Coronal CT showing a small compound odontoma (*arrow*).

frequently in men under 25 years of age, is solitary, and usually is located in the molar or premolar region, with the mandibular first molar being most frequently involved. Benign cementoblastomas are most often associated with permanent teeth, but primary teeth may also be affected.

Radiographically, the tumor is well defined, with central dense radiopaque material being attached to the tooth root and a surrounding radiolucent zone of uniform width, which represents the peripheral nonmineralized tissues of the formative cellular layers.[68] These tumors have a tendency to expand the cortical bone of the jaws. The lesion is easily enucleated because it is benign and surrounded by a capsule.

The lesion more anteriorly demonstrates an ill-defined lucent area beneath the molar teeth. There is extension of this myxoma through the cortex of the mandible, best illustrated inferiorly near the angle of the mandible.

BENIGN NONODONTOGENIC TUMORS

Benign nonodontogenic tumors are not unique to the jawbone, being found in other parts of the skeleton as well. Their radiographic appearance in the jaw does not differ significantly from their appearance in other bones if one takes into account any abnormalities the lesions may cause to adjacent tooth structures. The discussion of these lesions is based mainly on their tissue of origin.

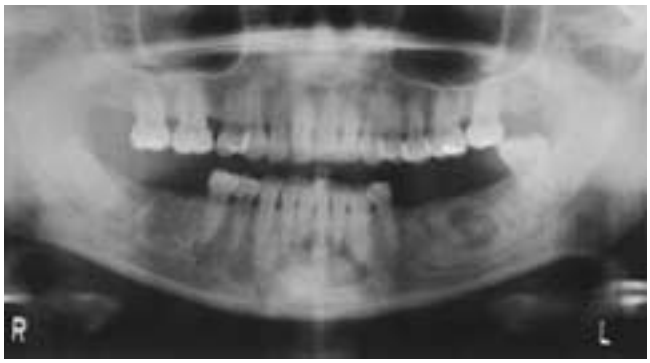
Exostosis

Exostoses are localized outgrowths of bone that vary in size and can be either flat, nodular, or slightly pedunculated protuberances on the surface of the mandible or maxilla.[69–71] The cause of these exostoses of the jaw is unknown. Three types of exostosis are identified according to their location: the torus mandibularis, the torus palatinus, and multiple (maxillary) exostoses. They resemble the compact form of osteoma. The exostoses are differentiated primarily by their typical location.



VIEW IMAGE

FIGURE 17-42 Periapical cemental dysplasia. Pantomogram of the mandible shows multiple sclerotic foci within the mandible, especially at the symphysis and body on the left. Some of these sclerotic areas merge imperceptibly with the mandible. Other densities are surrounded by a lucent ring. The radiographic appearance shows the evolution from lucent areas in the early stages, to mixed stages, and finally to the sclerotic stage.

Radiographically, exostoses are recognized as areas of increased bony density projecting from the mandible or maxilla. Exostoses composed of compact bone are of uniform radiopacity, whereas those that contain a marrow space have trabeculations. Some exostoses are difficult to demonstrate radiographically, particularly small ones and those that are superimposed on the teeth. An enostosis is a related lesion that originates from the inner cortex of the jaw as an area of osteosclerosis.

Torus mandibularis is an outgrowth of bone on the lingual surface of the mandible (Figs. 17-46 to 17-48). It usually is situated above the mylohyoid line, opposite the bicuspid teeth.[44] The size, shape, and number of exostoses vary. The mandibular tori are usually bilateral, but this condition has been found to be unilateral in 20% of cases. The reported incidence in the United States ranges between 6% and 8%, with no sex predilection.

Torus palatinus is a flat, spindle-shaped, nodular or lobular exostosis that arises in the middle of the hard palate (Figs. 17-49 and 17-50). The cause is unknown, but some theories suggest that it may be a hereditary condition.[63, 64] The incidence in the United States varies between 20% and 25%, with women being affected more often. Although torus palatinus may occur at any age, its peak incidence is before the age of 30 years. Radiographically, the torus palatinus is radiopaque, with distinct borders, and is composed of either dense compact bone or a shell of compact bone with a center of cancellous bone. Often a midline suture can be identified through the lesion. Surgical removal is indicated if the torus interferes with swallowing or if a denture must be constructed for prosthetic tooth replacement.

Copyright © 2003, Mosby, Inc. All rights reserved.

Multiple exostoses of the maxilla (Fig. 50) arise from the buccal or lingual surfaces of the maxilla, primarily in the molar region.[71] They appear as small, nodular, bony masses.

Osteoma

An osteoma is a benign neoplasm composed of compact or cancellous bone, usually in an endosteal or periosteal location.[72–74] These tumors vary greatly in size and, if large, can cause disfigurement. The average age at occurrence is 50 to 60 years, and twice as many women as men are affected. These lesions occur most often in the paranasal sinuses, especially in the frontal and ethmoid sinuses. The next most common site is the jaw, and the mandible is affected more often than the maxilla.

Osteomas have a characteristic radiographic appearance. They are well-circumscribed, sclerotic bony masses attached by a broad base or pedicle to the surface of the mandible. Root absorption may occur when the osteoma is located in the vicinity of a tooth. The need for surgical removal is determined clinically because osteomas have not been found to become malignant.

Gardner's syndrome, which is inherited as an autosomal dominant trait, consists of multiple osteomas, multiple colonic polyps, epidermoid and sebaceous cysts, desmoid tumors of the skin, and impacted supernumerary and permanent teeth (Fig. 17-51). The multiple osteomas often precede the onset of the colonic polyps, and these polyps almost always eventually become malignant.[75–78] Osteomas have a predilection for the frontal bone, maxilla, and mandible, although they may be observed in any of the bones of the cranium or facial skeleton. Osteomas of the jaw usually appear early in life, most often in the second decade.

Osteochondroma

An osteochondroma is a benign lesion thought to arise from overgrowth of cartilage at a growth site. These lesions have been reported most frequently in the coronoid and condylar processes.[79, 80] Radiographically, they usually appear as radiopaque extraosseous projections. Although it has been suggested that these tumors are very slow-growing and may have malignant potential, this is not universally agreed upon. Complete surgical removal is the treatment of choice, and recurrence is rare.

Chondroma

Chondromas are slow-growing lesions that presumably arise from cartilaginous remnants in bone.[81] They produce destruction of normal bone and appear as lytic lesions in the body of the mandible and occasionally in the condyle. Full delineation of condylar lesions often requires CT or MR imaging. Histologically, they are neoplasms of hyaline cartilage that are usually homogeneous in appearance. Therefore, these lesions have high signal intensities on T2-weighted MR images, while T1-weighted MR images often shows low signal intensities similar to those of water. It may be difficult to distinguish between benign and malignant lesions when unusual mitotic activity is identified. Surgical removal with wide margins is the preferred treatment.

Synovial Chondromatosis

Synovial chondromatosis is a proliferation of synovial tissues with the formation of cartilaginous particles in the

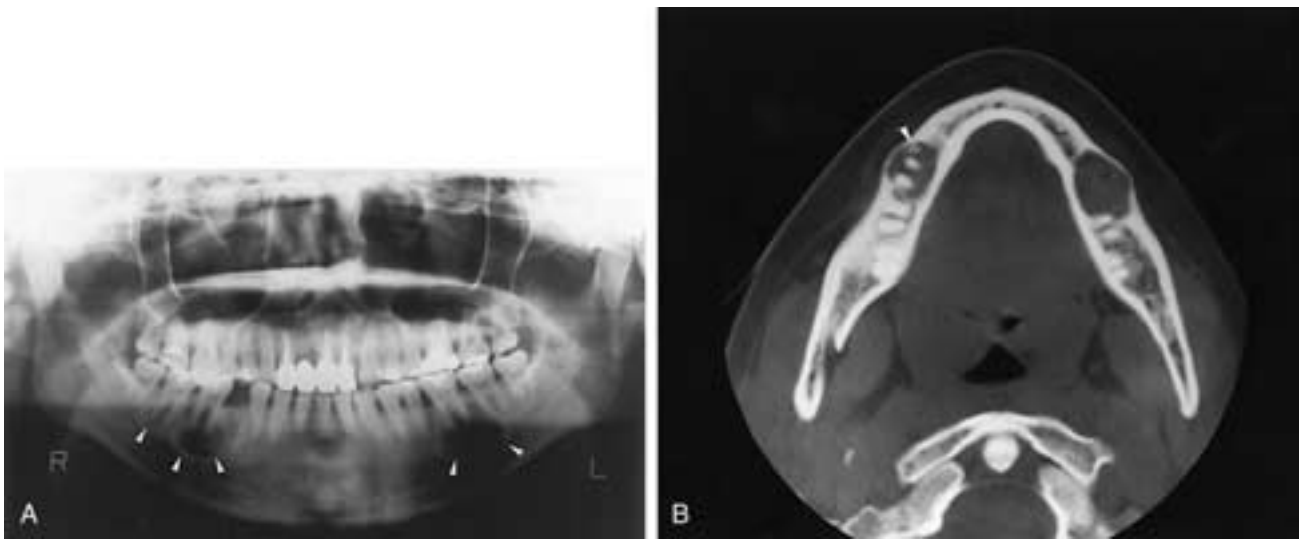


FIGURE 17-43 Cemental dysplasia in the mandible. **A**, Pantomogram shows multiple periapical radiolucent lesions with radiopaque areas in the mandible (*arrowheads*). Preoperative diagnosis of cemental dysplasia is made by radiography, and MR imaging is not useful for differentiation.

synovium that can ossify and migrate into the TMJ space. Symptoms vary widely, but patients often complain of intermittent periarticular swelling, pain, and limitation of motion. Radiographic findings depend on the extent of the proliferative process and include joint effusion, anatomic derangement of the normal joint structures with widening of the joint space, irregularity of the joint's articular surfaces, and evidence of calcified or ossified particles within the joint space. Surgical removal of the lesion and synovectomy is the usual treatment, and in most cases the articular disk does not need to be reconstructed. In cases where reconstruction is deemed necessary, the most common procedure is a vascularized, pedicled temporalis muscle flap interposed between the condyle and the articular fossa of the temporal bone (see Chapter 18).

Giant Cell Lesions

Giant cell lesions of the maxillofacial skeleton make up a continuum of clinically distinct yet histologically very similar pathologic conditions.[82–89] Giant cell granuloma, giant cell tumor, brown tumor of hyperparathyroidism, and cherubism are clinically separate entities that fall into this category. Whether or not the ''true'' giant cell tumor of long bones exists in the maxillofacial skeleton continues to be controversial. Most authors now believe that there is an analogy between the two lesions and that they may represent

FIGURE 17-46 Torus mandibularis. Dental view demonstrates bony exostoses along the lingual surface of the mandible bilaterally.

VIEW IMAGE

a spectrum of a similar pathologic process. Several groups have carried out histomorphometric studies to examine the biologic behavior of these lesions to classify them more correctly, with the aim of correlating histologic and clinical behavior. Based on the clinical, radiologic, and histologic findings, the designation of giant cell lesions of the jaws as either aggressive or nonaggressive may be of more help to the clinician than designation of all of these lesions as belonging to one group.

Giant cell granulomas occur most frequently in the second and third decades of life, and they occur twice as frequently in women as in men. Painless swelling is the most

common symptom, but some lesions may be noted as an incidental finding during routine radiographic screening. The mandible is affected in about two thirds of the reported cases, with most tumors being located in the anterior mandible between the second premolar and the second molar, often with extension across the midline. On occasion, these lesions may exhibit a more aggressive clinical and radiographic appearance.

Radiographically, the lesion most often has a radiolucent, multilocular, honeycombed appearance, with tiny bony septae traversing the involved area (Fig. 17-52). When present, the various loculi are irregular in shape and vary in size; however, unilocular tumors without trabeculation do occur.

VIEW IMAGE

FIGURE 17-49 A torus palatinus (*arrow*) extends from the midline of the palate.

Often there is rather marked expansion, with thinning of the cortical plates, and perforation may occur in large lesions. If the mass is adjacent to teeth, displacement and root resorption are seen. Lesions, especially those in the antral region, produce ''ground-glass'' radiopacities and occasional calcifications (Figs. 17-53 and 17-54). Treatment modalities include enucleation and curettage with local osteotomy, chemical cautery, electrocautery, cryotherapy, and en bloc resection.[82, 83] Calcitonin, interferon alpha, and intralesional steroids are newer modalities that have been somewhat successful in treating more aggressive and recurrent lesions.

LANGERHANS' HISTIOCYTOSIS (HISTIOCYTOSIS X)

Histiocytosis X is a spectrum of diseases with a proliferation of lipid-laden Langerhans' cells (histiocytes) accompanied by a significant inflammatory response.[90–99] This process can be focal or widely disseminated, acute or chronic, and benign or malignant. The cause of this disease remains unknown, although genetic factors, infectious agents, and immunologic abnormalities have been suggested. In 1987, the Writing Group of the Histiocyte Society proposed that the term *Langerhans' cell histiocytosis* replace *histiocytosis X* because Langerhans'-type histiocytes are a unique identifier for this disease.[98] Based on the clinical presentation, three variants have been described: Letterer-Siwe disease (disseminated acute histiocytosis), Hand-Schuller-Christian disease (disseminated chronic histiocytosis), and eosinophilic granuloma (localized histiocytosis).

Letterer-Siwe Disease

Letterer-Siwe disease is the acute, widely disseminated form of histiocytosis X.[95] It is generally fatal and usually

VIEW IMAGE

occurs in infants under 1 year of age. Lesions are usually present in several bones and may appear as multiple small, rounded radiolucencies with well-defined borders. If teeth are present in the affected regions, they are frequently mobile, and there is associated gingival bleeding.

Hand-Schuller-Christian Disease

Hand-Schuller-Christian disease is the disseminated chronic skeletal and extraskeletal form of histiocytosis X.[96] It is the intermediate stage between eosinophilic granuloma and Letterer-Siwe disease. It occurs mostly in children (twice as often in boys as in girls) from the first to the tenth year of life. The three classic signs of the disease (single or multiple sharply defined calvarial defects, unilateral or bilateral exophthalmos, and diabetes insipidus) are noted in about 10% of patients. Other organs such as the lymph

nodes, liver, spleen, lungs, and skin may be involved. The first indication of the disease often appears in the oral structures, either in the form of red, spongy gingiva or premature loss of teeth. The typical radiographic appearance is one of irregular, lucent defects in the mandible and maxilla. The affected teeth appear to be ''floating in space'' as a result of marked destruction of the alveolar bone. The disease is slowly progressive, and the mortality rate may be as high as 60%.

Eosinophilic Granuloma

Eosinophilic granuloma is the mildest and most favorable form of histiocytosis X.[97] There is a male predilection, with a peak frequency in the third decade of life. The average age of patients with eosinophilic granuloma of the jaw is higher than that of patients with lesions in other parts of the body, and frequent sites are the skull and the tooth-bearing areas of the mandible. The lesion may be an incidental radiographic finding and may manifest as local pain, swelling, tenderness, or fever and general malaise. Eosinophilic granuloma of the mandible causes well-demarcated areas of osteolysis that may appear ''punched out.'' Maxillary lesions usually are not as well demarcated as those in the mandible.

The area of bone involvement is characterized by irregular lucent patches having no reactive sclerosis but often showing cortical destruction (Fig. 17-55). These patches may appear as single or multiple areas of rarefaction simulating jaw cysts, periapical granulomas, or periodontal disease (Fig. 17-56). Early radiographic findings include

VIEW IMAGE

destruction of the alveolar bone crest and interdental septum and loss of the cortical outline of a tooth follicle or the lamina dura. The teeth in the involved regions become loose, float in space, and are exfoliated.

Unifocal lesions may be curetted and packed with cancellous bone.[99] With several recurrences or persistent residual granulomas, low-dose irradiation and cortisone treatment may be beneficial. Cytostatic agents (vinblastine, cyclophosphamide, and etoposide) also have been used successfully. Other treatment modalities include immunotherapy (suppressin A, cyclosporin), hormonal therapy, intralesional steroids, and bone marrow transplantation.

FIBROOSSEOUS LESIONS

Fibrous Dysplasia

Fibrous dysplasia is a lesion of unknown cause, diverse histopathology, and uncertain pathogenesis that is most commonly seen in the first three decades of life.[100–106] It occurs more frequently in the maxilla than in the mandible, where it usually arises in the posterior regions of the bone. There are considerable microscopic variations in the different lesions, as evidenced by fibrous tissue alternating with trabeculae of coarse woven bone and less organized lamellar bone. The three forms of fibrous dysplasia are monostotic fibrous dysplasia, polyostotic fibrous dysplasia (in which multiple bony lesions, often unilateral, occur), and Albright's syndrome.

Monostotic fibrous dysplasia occurs equally often in males and females and is encountered frequently in children and young adults, with a mean age of 27 years.[102] The clinical symptom usually is painless swelling of the involved bone; however, neurovascular compromise may cause symptoms. Typically, there is involvement of the jaw, as noted by bulging of the labial or buccal plates, malalignment and displacement of teeth, protuberance of the maxilla, or enlargement of the maxilla or zygoma with proptosis. There also can be skull base disease.

Polyostotic fibrous dysplasia manifests early in life, often with an insidious onset. The disease is characterized by bone deformities, and in some cases there is associated bone pain. In this form of fibrous dysplasia, the skull and face are frequently involved, often with obvious asymmetry secondary to bone expansion. Jaw involvement develops slowly and usually presents with facial deformity, overgrowth of the alveolar bone, and displacement of teeth. There can be marked enlargement of the maxilla, with involvement of the maxillary sinuses, nasal cavities, orbit, and base of the skull. Craniofacial fibrous dysplasia is generally not a functionally devastating disease unless the lesion involves the orbit and skull base; when this happens, blindness, pituitary dysfunction, and vital neurovascular compromise may occur.

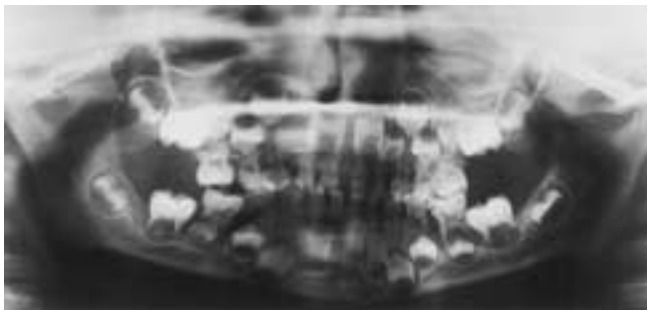

FIGURE 17-56 Diffuse eosinophilic granuloma in the mandible. Pantomogram of the mandible shows loss of the lamina dura of erupted and partially erupted tooth follicles. This is especially evident at the second lower right molar tooth.

The lesion contains multiple consistencies including soft tissue, bone, and perhaps cartilage. **A**, Axial image with multiple punctate areas of mineralization (*arrow*). The low density may represent fibrous tissue or a cystic component. **B**, Coronal image shows small foci of calcifications (*arrowhead*) that may represent chondroid matrix. This makes differentiation from chondrosarcoma difficult. The lateral part of the abnormality (*arrow*) has a typical ''ground glass'' appearance.

Albright's syndrome is a developmental defect of unknown cause. It consists of cutaneous pigmentation, precocious puberty, and multiple skeletal lesions. Young girls are affected most often.

The radiologic appearance of fibrous dysplasia can vary considerably, usually depending on the degree of bone present within the lesion (Figs. 17-57 to 17-60). One appearance is that of a unilocular or multilocular, primarily radiolucent lesion with a well-defined border. Interspersed bony trabeculae are often present within the lucent area, rendering the lesion partially radiopaque (Fig. 17-61). Another appearance is that of a marked homogeneous increase in bone density associated with bone expansion, which reflects the predominant histologic finding of bony

trabeculae with only a few scattered areas of fibrous tissue (Fig. 17-62). This is sometimes referred to as a ground-glass appearance, which is more evident on CT. Cystic lesions of appreciable size cause thinning and remodeling of the cortex, but they rarely perforate the cortex or produce new periosteal bone. Although the lesion may cause resorption of the roots of erupted teeth, this is rare. MR imaging findings also depend on the variety of components of the disease, especially on T2-weighted images. The fibrous components often shows enhancement after contrast administration. If the lesion has rich cartilaginous components or cystic changes, its signal intensities can be brighter: the former show gradual enhancement, while the latter show no enhancement.

The disease is usually self-limiting, often not progressing after the third decade of life. Surgical treatment usually is limited to a cosmetic debulking and recontouring of the bone. However, an accelerated progression of the disease has been noted with early and aggressive surgical manipulation, sometimes mandating additional surgery. Only small lesions can be removed by enucleation. Because there is a low incidence of malignant transformation of fibrous dysplasia, regular and careful follow-up should be maintained.

Ossifying Fibromas (Cemento-Ossifying Fibromas, Cementifying Fibromas)

The ossifying fibroma is an encapsulated, benign neoplasm consisting of fibrous tissue that contains various amounts of irregular bony trabeculae.[107, 108] As the lesion matures, the areas of ossification increase in number and coalesce, accounting for the lesion's progressively increasing radiodensity. These lesions may be difficult to distinguish from fibrous dysplasia histologically, but they are sharply demarcated and not uncommonly encapsulated masses that behave as benign neoplasms. In the recent WHO classification,[3] cemento-ossifying lesions (both neoplastic and dysplastic) are listed in the category of neoplasms and other lesions related to bone, although benign cementoblastoma, generally accepted as being essentially cementogenic, has been included in the neoplasms and other tumors related to the odontogenic apparatus category. Ossifying (cemento-ossifying) fibroma is found more often in females and may occur at any age, but it is most common in the third and fourth decades of life. The lesion develops predominantly in the mandible and is usually situated at the roots of the teeth or in the periapical region. It generally is asymptomatic, but a progressive increase in size may eventually cause swelling of the jaw.

Radiographically, the lesion usually has a distinct boundary, unlike fibrous dysplasia, and in the early stages it presents as a lucent area. As the lesion matures, bone densities appear, transforming the lesion into a radiopaque mass surrounded by a ''halo'' of less ossified tissue (Fig. 17-63). One aggressive variety of ossifying fibroma is referred to as juvenile ossifying fibroma. This term designates a very actively growing destructive lesion that is histologically identical to the routine ossifying fibroma. This lesion affects individuals younger than 15 years of age and occurs exclusively in the maxilla.

The treatment of ossifying fibroma is usually surgical enucleation. However, for some forms of this lesion, especially the juvenile form that is prone to recur, broader surgical resection should be considered.

Paget's Disease (Osteitis Deformans)

Paget's disease of bone is a chronic disease characterized by abnormal functioning of osteoblasts and osteoclasts resulting in poorly mineralized and deformed bones.[109, 110] There is a slightly higher male predominance, and the incidence increases with age. There are also reports of an occasional familial pattern. Although the exact cause remains unknown, numerous theories have been proposed regarding its development, including a slow viral infection, hormonal abnormalities, a vascular anomaly, an autoimmune-type connective tissue disorder, and a true neoplasia. Malignant transformation, although not a common occurrence, has been reported in the jaws and is a constant concern. This is of particular concern if the region has been previously irradiated.

In the craniofacial skeleton, involvement of the skull, maxilla, and mandible is common. Headache, dizziness, hearing loss, and other cranial nerve abnormalities may result from the skull base involvement. The maxilla is involved more commonly than the mandible. The jaw lesions cause bone enlargement, separation of teeth with generalized widening of the interdental spaces, ill-fitting dentures, and frequently neuralgia-type pain.

Radiographically, the jaw lesions have a variable appearance, depending on the stage of disease progression. There can be ''punched-out'' radiolucent areas, mixed areas giving a ''cotton wool-like'' appearance, and more densely sclerotic areas. The jaw lesions frequently show evidence of

Copyright © 2003, Mosby, Inc. All rights reserved.

rarefaction and sclerotic change in the alveolar bone, with loss of the lamina dura surrounding the teeth and hypercementosis of the roots of teeth. Radionuclide scanning can identify the presence of disease based on the presence of areas of biologic activity. Laboratory findings typically include elevations in serum alkaline phosphatase and urinary hydroxyproline. Serum calcium and phosphorus levels are usually normal.

Clinical management may consist of no more than closely following the patient. When more severe disease exists or when the bone lesions in the craniofacial skeleton cause symptoms, therapeutic intervention is usually indicated. Nonsurgical treatment can include steroids and the use of calcitonins and diphosphonates. Surgical procedures must be carried out with great care because the abnormal bone is often very vascular, and significant bleeding can occur.

VASCULAR LESIONS

Vascular lesions of the head and neck are a perplexing group of problems that have generated significant debate and confusion regarding terminology and classification.[111–117] Descriptive, anatomic-pathologic, and embryologic classification schemes have been devised and debated and generally have not offered clinicians significant treatment guidance. The classification developed by Mulliken and Glowacki in 1982 is based on the cellular kinetics of the anomalous vessels and provides a diagnostic and therapeutic approach based on the biologic behavior of the lesion.[114] In this classification, two entities exist: hemangiomas and vascular malformations.

Hemangioma

Hemangiomas are usually not identified at birth, but they appear soon thereafter. They are present in 12% of all children by 1 year of age. They go through a rapid proliferation phase during the first year of life followed by a much slower involution phase, which usually reaches partial or complete resolution by 5 to 7 years of age.

Hemangiomas are 2 to 2½ times more common in females than in males, and there is no racial predilection. Hemangiomas are found most often in the skull and vertebrae, and although common in the head and neck, they are rarely located in the jaw. They are benign tumors with vessels that have marked endothelial turnover, and there are increased numbers of mast cells that are thought to play a role in the pathophysiology of these lesions.

Although most hemangiomas can be diagnosed by the history and physical findings, some are difficult to fully evaluate clinically and warrant imaging studies. Radiographically, hemangiomas of the mandible appear as ill-defined radiolucent lesions usually involving the inferior alveolar canal (Fig. 17-64). Some lesions may have a cystic or occasionally a multilocular shape. CT and MR imaging are particularly helpful for deeper lesions and those thought to involve bone. Doppler ultrasound and angiography may also be employed. Angiography of hemangiomas shows a well-circumscribed mass, usually with prolonged parenchymal staining and tissue blush.

Treatment is based on correctly identifying the lesion and distinguishing it from a vascular malformation. Kaban and Mulliken pointed out, in their review of vascular anomalies of the maxillofacial region, that many reported hemangiomas were in fact vascular malformations.[113] Management of maxillofacial hemangiomas often consists of counseling and

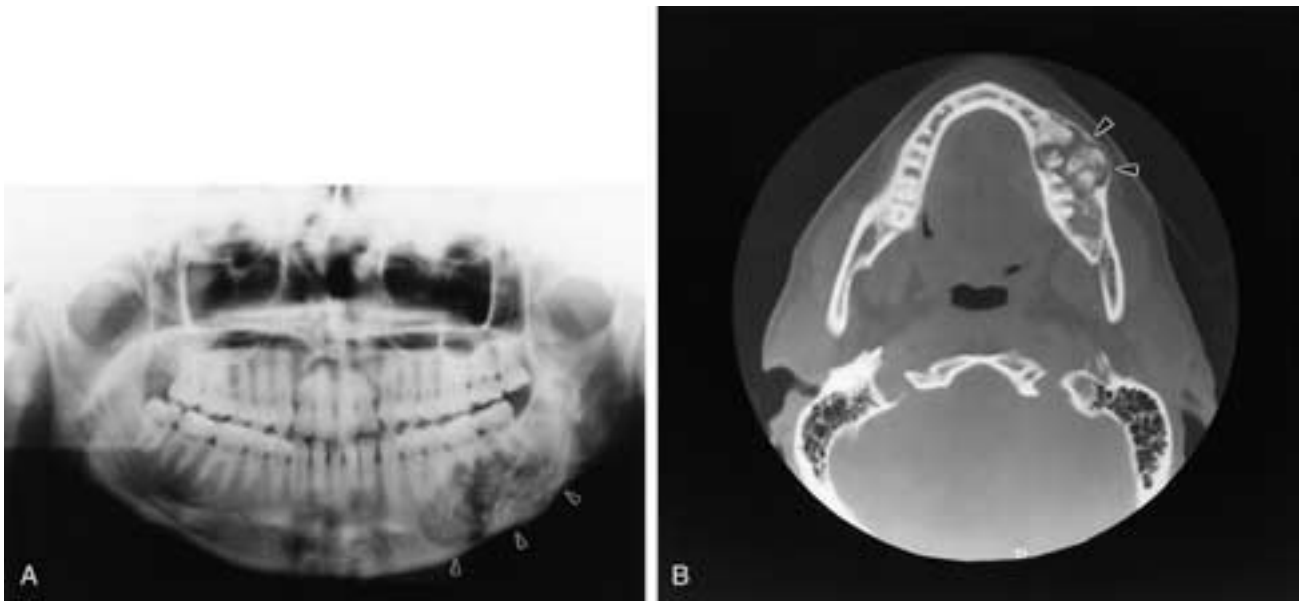

FIGURE 17-63 Cemento-ossifying fibroma in the mandible. **A**, Pantomogram shows a well-defined mixed radiolucent-radiopaque lesion (*arrowheads*). **B**, Axial CT (bone window setting) demonstrates a buccal expansile lesion with some calcifications in the mandible. parental support along with observation. If significant functional problems ensue, treatment consists of steroid therapy, compression therapy, radiotherapy, embolization, and treatment with interferon alpha.[116, 117] Surgery is reserved for small lesions and as a secondary procedure to correct cosmetic deformities.

Vascular Malformation

Vascular malformations are usually present at birth, but they may not be clinically evident until some inciting event occurs.[114] Their growth parallels normal body growth and is influenced by numerous additional factors. There is no sex predilection. Vascular malformations can be composed solely of capillary, venous, arterial, or lymphatic tissues or can be a combination of these tissues. They are subdivided into high-flow and low-flow lesions based on their clinical and angiographic patterns. In the maxillofacial region they frequently involve bone.

Radiographically, the lesion appears as a radiolucent area, often traversed by delicate bony trabeculae forming variously sized small cavities. In large vascular malformations the cortex may be thinned, remodeled, or eroded.[108] If the trabeculae are arranged in a radiating pattern, a sunburst or spoke wheel appearance results. In some cases, there may be a single radiolucent lesion with a sclerotic or ill-defined border that simulates a cyst. Root absorption, loss of the lamina dura, and exfoliation of teeth have also been reported, and a bruit may be heard or a thrill palpated over the lesion. Spontaneous bleeding around the involved teeth is a problem in the jaws.

Management of vascular malformations mandates a thorough knowledge of the pathologic process and the relevant anatomy. Small lesions may be treated with sclerosing agents, radiotherapy, cryotherapy, laser treatment, or conventional surgical techniques. Larger lesions, particularly high-flow and arteriovenous malformations, are best treated with embolization techniques, with or without surgical resection.

NEUROGENIC TUMORS

Benign neurogenic tumors, which include schwannomas (neurilemommas), neurofibromas, and traumatic neuromas, occasionally are found centrally within the jaw.[118–121] They may occur at any age, and there is little or no sex predilection. Most of these slow-growing lesions arise in the mandible and cause pain or paresthesia.

A schwannoma is usually encapsulated and composed of two distinct histologic components: Antoni type A tissue and Antoni type B tissue.[119] A neurofibroma arises from the connective tissue sheath of nerve fibers and has axons traversing the unencapsulated tumor.[118, 119] It may occur as a solitary lesion or as multiple lesions associated with neurofibromatosis. Solitary neurofibromas may originate in the oral mucosa or may occur within the jaws.

Copyright © 2003, Mosby, Inc. All rights reserved.

Radiographically, these lesions may present as solitary radiolucencies associated with the inferior alveolar canal or as multilocular radiolucencies that produce extensive bone damage, with cortical remodeling and even perforation. On occasion, the intraosseous tumor may perforate the cortex of the jaw and extend into the overlying soft tissues. A schwannoma, arising from the nerve within the inferior alveolar canal, may cause bulbous, elongated enlargement of the canal, and a neurofibroma adjacent to bone may produce a saucer-shaped erosive defect on the surface of the bone.

Treatment is surgical but depends on the size and location of the lesion. Smaller lesions can often be removed without significant damage to the nerve or surrounding tissues and without the need for major reconstructive surgery. Larger lesions, especially those with significant bone involvement, usually require larger surgical exposure with enucleation or en bloc surgical resection, often with additional treatment modalities such as cautery or cryotherapy of the bone. When these techniques are needed, surgical reconstruction is mandatory, often with a microsurgical nerve repair.

MALIGNANT TUMORS

Malignant tumors can be grouped into three categories: (1) lesions that invade the mandible and maxilla secondarily from adjacent soft-tissue structures of the oral cavity and sinuses, (2) tumors that arise primarily within the mandible and maxilla, and (3) metastatic tumors from distant sites. The radiographic appearance of malignant lesions often allows differentiation from benign tumors and cysts; however, a biopsy is necessary to establish the final diagnosis. For proper treatment planning, it is important to assess the extent of the malignant tumor radiographically before surgery or radiation therapy. CT and MR imaging have proven valuable in assessing the extent of tumors outside the mandible and maxilla, as well as in assessing disease extension within the bone or metastases to the neck.

Carcinoma

Most carcinomas encountered in the jaw originate in the oral cavity (lip, tongue, buccal mucosa, gingiva, floor of the mouth, and palate) and maxillary sinuses, and they secondarily invade the mandible and maxilla.[122–125]

Radiographically, the osseous involvement manifests early at the alveolar ridge with a saucer-shaped erosive defect. This defect may be shallow and well defined, but in time an irregular cavity can be formed. There is usually no evidence of bony sclerotic or periosteal reaction. Therefore, superficial erosion of the alveolar crest in the tooth-bearing regions may initially mimic periodontal disease. Radiographically, carcinoma usually appears as a radiolucency with irregular margins (Fig. 17-65). Permeative disease extension may create a ''moth-eaten'' appearance. The radiographic findings are nonspecific, and the tumor cannot be differentiated from other malignant lesions. Pathologic fractures are common complications in advanced cases.

Odontogenic carcinoma is a carcinoma arising within the bone without a lesion of the mucosa.[1] These rare malignancies arise from epithelial remnants left behind by the process of tooth formation, hence the use of the term *odontogenic*. Odontogenic carcinoma can be subcategorized according to its apparent origin. Malignant ameloblastoma represents transformation from a benign ameloblastoma. Primary intraosseous carcinoma arises without preexisting ameloblastoma. Some carcinomas may arise in preexisting odontogenic cysts.

Primary intraosseous carcinoma may develop from epithelial components that participate in the development of the teeth or from epithelial cells that become enclosed within the deeper structures of the jaw during embryonic development. About 90% of these lesions are found in the mandible; they occur more frequently in men than in women, and their peak incidence is in the sixth and seventh decades of life. Although uncommon, this lesion is now recognized as a distinct entity. The lesion typically has an irregular margin. No mucosal abnormality is seen.

Carcinomatous transformation of the epithelium in an odontogenic cyst is a rare event, although it has been reported in dentigerous cysts, radicular cysts, residual cysts, and keratocysts. None of the reported cases affected individuals over 40 years of age. Radiographically, the lesion resembles a cyst with a circumscribed margin. In the area of malignant degeneration the margin may become ill-defined, irregular, or moth-eaten.

Ameloblastoma is rarely malignant.[1–3] The WHO classification of 1992, however, does include malignant ameloblastoma[1] as a category. It defines malignant ameloblastoma as ''a neoplasm in which the pattern of an ameloblastoma and cytological features of malignancy are shown by the primary growth in the jaws and/or by any metastatic growth.'' There is controversy regarding exact terminology.[2, 126–128] Some advocate restriction of the term *malignant ameloblastoma* to an ameloblastoma that, although histologically benign, shows a malignant nature by metastasizing. The metastasis shows the histologic pattern of the original tumor, again without cytologic indicators of malignancy. There are tumors that do have typical cytologic findings of malignancy including increased and abnormal mitoses, nuclear pleomorphism, and so on. The term *ameloblastic carcinoma* has been advocated for these rare lesions. They may metastasize as well. Neither term should be applied to a histologically benign tumor that simply shows aggressive local extension even though involvement of key contiguous structures may be life-threatening. The radiologist should simply realize that the controversy related to terminology exists and that clarification of terms is appropriate in the individual case or in reports in the literature.

Malignant variants of ameloblastoma may arise de novo or in relation to a preexisting ameloblastoma. The lesions are most commonly found in the jaw. The imaging findings may be inseparable from those of benign ameloblastoma, but locally aggressive tumors can have a more irregular margin.

Other rare malignant epithelial lesions include clear cell odontogenic carcinoma and malignant odontogenic ghost cell tumor. The clear cell lesion must be distinguished from metastatic renal cell carcinoma. Immunohistochemical markers help make this differentiation. The term *malignant ghost cell tumor* (odontogenic ghost cell carcinoma) has

Copyright © 2003, Mosby, Inc. All rights reserved.

been applied to a histologically malignant solid tumor related to calcifying odontogenic cyst.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma can also arise within the jaw.[129–132] Women are affected twice as often as men, and the average age at diagnosis is 46 years. The radiographic changes consist of ill-defined lytic or multilocular cystic areas that are often indistinguishable from squamous cell carcinoma (Fig. 17-66). CT and MR imaging are extremely helpful in delineating the extent of disease in the mandible and the surrounding soft tissues, as well as in identifying cervical lymph node involvement. An accurate tissue diagnosis is also mandatory to plan appropriate therapy, which usually consists of combined radiation therapy, chemotherapy, and surgery. A pretreatment oral examination and dental evaluation is necessary to diagnose any tooth and gum pathology that needs to be eliminated before initiating radiotherapy or chemotherapy. Also, when surgical resection is planned, appropriate prosthetic reconstruction strategies can be planned before surgery, allowing better functional results and greater patient satisfaction.

Metastatic Jaw Tumor

Metastatic tumors to the mandible or maxilla may be the first indication of an occult malignancy or the first evidence of dissemination of a known primary tumor. Patients with metastatic lesions may be asymptomatic or may complain of symptoms similar to those found with other primary malignant tumors. Metastases to the mandible are four times more frequent than those to the maxilla, and the most common primary tumors are in the breast, lung, kidney (hypernephroma), thyroid, prostate, and stomach.

FIGURE 17-65 Squamous cell carcinoma of the anterior mouth with secondary invasion of the mandible. **A**, Axial CT of the mandible (bone window setting) shows an erosion in the central and anterior parts of the mandibular symphysis. **B**, Axial CT (soft-tissue window setting) demonstrates a lesion in the anterior mouth, with extension into the mandible. Again, note the erosion in the anterior cortex and adjacent medullary portion of the mandible. **C**, Another patient. The surrounding buccal bony cortex is destroyed (*arrowheads*). (Courtesy of Dr. T. Kurabayashi, Dept. of Dental Radiology, Tokyo Medical and Dental University, Tokyo.)

In most instances, the bone destruction caused by a metastatic lesion is radiographically similar to that caused by a primary tumor, and the area of destruction within the mandible may be localized, bilateral, or diffuse (Fig. 17-67). On occasion a mixed lesion of lytic and blastic areas may be encountered, usually from a carcinoma of the breast. In rare cases, metastasis from a carcinoma of the prostate may cause diffuse osteoblastic change.

When metastatic disease is suspected, a thorough search for the primary site and other sites of metastatic involvement should be immediately initiated, and a biopsy for definitive tissue diagnosis should be performed. A team approach with coordination among the internist, radiologist, oncologist, surgeon, and other health care providers involved in the care of the cancer patient is the optimal approach to an often difficult problem.[133–140]

Sarcoma

Osteogenic Sarcoma

Osteogenic sarcoma is a malignant tumor of the bone in which neoplastic cells produce a variable amount of osteoid.[141–147] According to the predominant tissue observed microscopically, these lesions are classified as osteoblastic, chondroblastic, or fibroblastic. About 6.5% of osteogenic sarcomas arise in the jaw.

Primary osteogenic sarcoma usually affects children and young adults, with a peak incidence in the second decade of life. However, osteogenic sarcomas of the mandible and maxilla have their peak incidence a decade later. The mandible is affected more often than the maxilla, and there is no sex predominance. The main symptoms are swelling

and pain, but paresthesias, loose teeth, and bleeding have been reported.

Radiographically, osteogenic sarcoma can cause lytic bone destruction with indefinite margins (osteolytic type) (Fig. 17-68), an area of sclerosis (osteoblastic type) (Figs. 17-69 and 17-70), or a mixed pattern. The osteoblastic type is the most common one in the jaw. Some osteosarcomas show a sunburst effect caused by radiating mineralized tumor spicules (Fig. 17-71). Cortical breakthrough, with tumor outside the jaw, is a common finding in advanced cases. Because a symmetrically widened periodontal membrane may be the earliest radiographic finding of osteogenic sarcoma of the jaw, this tumor must be differentiated from other diseases such as sclerodoma or acrosclerosis that also cause widening of the periodontal membrane.

Osteosarcomas can be easily assessed by CT because this modality identifies lesions that contain calcium, osteoid, or both. However, the extent of tumor spread within the marrow space or outside of the jaw may be seen better with MR imaging. Patients with mandibular osteosarcomas have a better prognosis than those with maxillary tumors; however, patients with mandibular or maxillary osteosarcomas are prone to develop either a recurrence or distant metastases, especially to the lungs. Treatment is surgical excision, usually followed by radiation therapy and possibly chemotherapy.

Fibrosarcoma

Fibrosarcoma of the jaw is a rare lesion that occurs predominantly in the mandible.[148, 149] Onset can occur at any age but is most common before the age of 50 years, with a peak incidence between 20 and 40 years of age. Among these tumors, peripheral and central fibrosarcomas have been differentiated. The rare central form most frequently develops in the mandibular canal and causes central bone

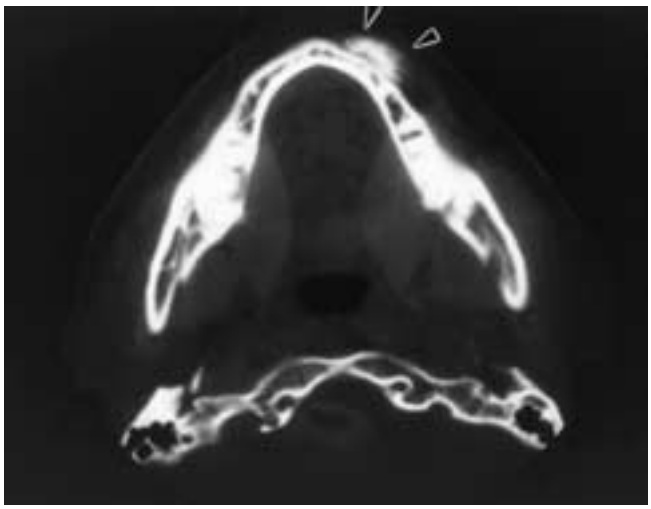
destruction, with gradual expansion leading to cortical erosion in larger lesions. The more prevalent peripheral type originates from the periostium or the periodontal membrane, frequently in the body and angle of the mandible. Radiographically, erosive changes are encountered at the alveolar ridge or at the inferior border of the mandible; the depth of the defect varies, depending on the stage of tumor development. Usually an extramandibular soft-tissue mass of variable size is palpated.

An ameloblastic fibrosarcoma has been described as a mixed epithelial/mesenchymal lesion.[2] Only the mesenchymal component is malignant. The epithelial component most closely resembles an ameloblastic fibroma. This lesion is extremely rare. The terms *odontogenic sarcoma* and *ameloblastic fibro-odontosarcoma* have been used to refer to similar lesions.[150]

The term *carcinosarcoma* has been applied to a rare lesion in which both the epithelial and mesenchymal components are malignant.



VIEW IMAGE

FIGURE 17-71 Osteogenic sarcoma in the anterior part of the mandible. Axial CT demonstrates a mass with periosteal reaction suggesting the typical ''sun-ray'' appearance in the mandible (*arrowheads*).

Ewing's Sarcoma

Ewing's sarcoma occurs predominantly in children and young adults between 5 and 25 years of age, and males are affected twice as frequently as females.[151–154] In one series of studies, jaw involvement occurred in 13% of cases, and this lesion occurs 10 times more frequently in the mandible than in the maxilla. Radiographically, the lesion has a mottled, irregular, lucent appearance, with sclerosis interspersed in a small percentage of tumors. Perpendicular bony spicules and extensive bone destruction may be found at the cortices. The characteristic onion-peel (onion skin) layering of new subperiosteal bone is often absent in the jaw. This tumor tends to metastasize early, often to multiple bony sites, making treatment difficult and the prognosis poor. Treatment usually involves a combination of radiotherapy and chemotherapy.

Malignant Lymphoma

Malignant lymphoma is derived from lymphocytes and reticulum (histiocytic) cells that are in different stages of development, and the disease can have either a regional or a systemic distribution.[155–157] Lymphomas in the head and neck occur predominantly in the neck nodes, oral cavity, nasopharynx, and occasionally in the sinuses. However, primary lymphoma of bone may occur in the mandible and

Copyright © 2003, Mosby, Inc. All rights reserved.

maxilla. Such bone lymphomas are predominantly histiocytic (large cell) lymphomas; they occur more frequently in the mandible than in the maxilla, and there is a male predominance. Radiographically, there are no pathognomonic findings. In the mandible, most often there are ill-defined lytic destructive areas of variable size (Fig. 17-72). Radiation therapy and chemotherapy are the primary treatment modalities.

Multiple Myeloma

Although single lesions may occasionally occur, multiple myeloma is characterized by multiple or diffuse bone involvement.[158–161] Myeloma occurs most frequently in patients 40 to 70 years of age, with males being affected twice as frequently as females. In patients with multiple myeloma of the jaw, mandibular lesions are far more common, and there is a predilection for the angle, ramus, and molar tooth regions. The typical radiographic appearance is that of ''punched-out,'' regular, circular, or ovoid radiolucencies with no circumferential bone reaction, especially when the skull is involved (Fig. 17-73). The cortex of the mandible may be perforated, but expansion of bone is not demonstrated. If the lesion is extensive, the entire bone may be destroyed, and bone destruction frequently is associated with hypercalcemia.

Treatment of multiple myeloma is primarily medical. Chemotherapy is the primary modality, often along with anabolic steroids, fluoride, calcium, and vitamin D. Solitary bone lesions most often are treated with radiation therapy. When surgery of jaw lesions is planned, consideration of the

patient's hematologic status is necessary to avoid untoward complications.

Leukemia

Leukemia may involve the jaw bones; in one series of patients with acute leukemia, 63% of cases had disease in the jaw.[162–164] An early radiographic finding is loss of the lamina dura with loosening of the teeth. This is often followed by varying degrees of lytic bone destruction (Fig. 17-74). Treatment is primarily medical management, and special attention should be paid to reducing the chance of oral infection and bleeding.

INFLAMMATORY CONDITION OF THE MANDIBLE

Osteomyelitis

Osteomyelitis, an inflammation of bone and bone marrow, may develop in the jaw as a result of odontogenic infection or the sequelae of various other conditions including underlying systemic diseases (immunocompromise) and focal injuries such as trauma, complicated fractures, and large doses of radiation therapy.[165–167] Development of osteomyelitis is rare in normal healthy people because of early administration of antibiotic therapy but can be associated with tuberculosis, diabetes, agranulocytosis, neutropenias, leukemia, uremia, sickle cell anemia, severe anemia, and febrile diseases such as typhoid.[165] The mandible is made up of a well-developed periosteum, a solid cortex, and a liberal spongiosa in the subapical region of the body of the mandible. The spongiosa also extends into the ascending ramus and the mental protuberance. The thick cortex is not easily penetrated by suppurative processes, and the infection can easily involve the whole mandible. Therefore, osteomyelitis of the mandible is more frequently and severely widespread than that of the maxilla.

Osteomyelitis may present radiographically as (1) suppurative osteomyelitis, (2) sclerosing osteomyelitis, (3) osteomyelitis with periositis, (4) tuberculous osteomyelitis, and (5) osteoradionecrosis.[160, 163] The disease may be either acute or chronic and may involve different clinical courses, depending on its nature.[166]

VIEW IMAGE

Copyright © 2003, Mosby, Inc. All rights reserved.

Suppurative Osteomyelitis

Acute suppurative osteomyelitis is sudden in onset and runs a very acute course. Such cases are associated with a severe constitutional reaction: high fever, rapid pulse, vomiting, delirium, and prostration.[165] In some instances, the disease may run a chronic course with slow onset, slight fever, and moderate pain. Radiologic findings can differ, depending on the course of the disease. On conventional radiographs, the bone usually has a normal appearance in the early stage (the first 8 to 10 days) of the disease. Later radiographs can show single or multiple irregular radiolucencies with poorly defined margins.[167] Chronic osteomyelitis shows a variety of bone reactions including completely radiolucent areas, mixed radiolucent and radiopaque areas, and completely radiopaque areas.

Bone scintigraphy and MR imaging can detect the early stage of the diseases.[168–170] Bone scintigraphy is useful in examining patients with suspected osteomyelitis. Radionuclide studies may signify the possibility of early-stage osteomyelitis before osseous changes are apparent on plain radiographs. Technetium-99m methylene diphosphonate (^{99m}Tc-MDP) bone scans are sensitive indicators of altered osteoblastic activity, but local disturbances in vascular perfusion, clearance rate, permeability, and chemical binding also affect imaging.[168] On standard ^{99m}Tc-MDP bone scans, however, it is sometimes difficult to differentiate soft-tissue uptake from bone uptake in patients with known cellulitis and possible underlying osteomyelitis. MR imaging has been reported to be useful in the initial diagnosis of osteomyelitis. Its MR imaging appearance depends on a variety of factors, including the patient's age, the type and virulence of the offending organism, and the presence of an underlying medical conditions.[170] In a normal population of patients over 30 years old, the entire medulla of the mandible usually shows high signal intensities suggesting fatty marrow when spin echo images are used.[171] On MR imaging, bone marrow lesions of osteomyelitis show low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. Sequestrum reveals low signal intensity on both T1- and T2-weighted images. Soft-tissue abnormalities are also evaluated on MR images, showing signal intensity patterns similar to those of marrow lesions, soft-tissue edema, blurring fat planes, and sometimes an abnormal fluid collection (Fig. 17-75).[169]

Contrast enhancement may improve the accuracy of the evaluation of osteomyelitis. Patients with active osteomyelitis show enhancement in medullary bony lesions. Infected areas are usually hypervascular, and the contrast moves into the extracellular fluid compartment because of altered vascular permeability.[172] This enhancement can be seen in soft-tissue components outside the infected areas of the mandible.

Osteomyelitis with Periostitis

Osteomyelitis with periostitis was erroneously described in the past as Garre osteomyelitis. It is simply a variant of osteomyelitis in which a periosteal reaction predominates, leading to subperiosteal deposition of new bone.[173, 174] This condition is characterized by the formation of new bone on the surface of the cortex over infected areas of spongiosa. The new bone formation is a response of the inner surface of the periosteum to stimulation by a low-grade infection that has spread through the bone and penetrated the cortex. The disease is seen almost exclusively in children and rarely occurs in persons over 30 years of age.[173] The mean age varies from 12 to 13.3 years, with a 1.4:1 male predominance. Patients have facial asymmetry resulting from a bony, hard swelling of the mandible.

Radiographs of this disease show laminar periosteal new bone (the so-called onion peel appearance), which is most evident on the inferior, buccal, or lingual aspect of the mandible (Fig. 17-76). In some cases, there may be accompanying radiolucent or osteosclerotic osteomyelitic changes, and small sequestra can often be seen. The differential diagnosis for a condition that resembles osteomyelitis with periositis includes Ewing's sarcoma, fibrous dysplasia, osteogenic sarcoma, infantile cortical hyperostosis, and peripheral osteomas.

Tuberculous Osteomyelitis

Tuberculous osteomyelitis is a specific infection caused by the acid-fast bacillus *Mycobacterium tuberculosis*. The oral tissue is involved by this organism via three routes: direct inoculation, extension from adjacent sites of infection, or hematogenous seeding.[175, 176] Radiographs of this disease show rarefaction with ill-defined borders and formation of sequestra, but sometimes there may be accompanying periosteal new bone formation (Fig. 17-77). The differential diagnosis includes nonspecific osteomyelitis, malignant tumors, and eosinophilic granuloma.

Sclerosing Osteomyelitis

Sclerosing osteomyelitis of the mandible is a predominantly proliferative reaction of bone representing resistance of the host to low-grade infection.[166] In patients with chronic sclerosing osteomyelitis, bone is deposited along the osseous cortex and existing trabeculae, resulting in thickening of the cortex and trabeculae and reduction or obliteration of the marrow spaces.[177]

Sclerosing osteomyelitis of the mandible has been divided into focal and diffuse types. The focal type, also known as periapical osteitis, is a common condition with a pathognomonic appearance. The radiographs show a well-circumscribed periapical radiopaque area of sclerotic bone (Fig. 17-78). The patient is easily cured by endodontic treatment or extraction of the affected tooth. The diffuse type is an uncommon disease that creates diagnostic and therapeutic problems.[177–179] Clinically, recurrent pain and swelling are typical symptoms. In the early stages of diffuse sclerosing osteomyelitis and in younger patients, the mandibular volume increases due to periosteal deposition of new bone. However, diffuse osteolytic changes are a more prominent feature than sclerosis. In the established chronic stages and in older patients with less prominent periosteal reactivity, the mandibular volume is reduced and sclerosis is more obvious, with smaller and fewer osteolytic zones. A distinctive radiographic and CT scan pattern is that of diffuse endosteal sclerosis with simultaneous involvement of the alveolar and basal bones and extension to the angle, ramus, or condyle, with indistinct borders. In the chronic stages, diffuse sclerosing osteomyelitis must be differentiated from other radiopaque lesions such as diffuse cemento-

sis, sclerosing cemental masses of the jaw, and florid osseous dysplasia in radiographic examinations.[176]

MR imaging shows abnormally thickened cortex with a signal void. There may be defects in the cortex and decreased signal intensity of bone marrow on T1-weighted images. The medullary cavity has increased signal intensity on T2-weighted images. Diffuse enhancement with gadolinium can be seen outside of the mandible when soft tissue is involved. In management, some authors report that an early diagnosis is of the utmost importance, and the patient should be kept under observation for several years.[177–179] However, similarities to other radiopaque lesions such as diffuse cementosis, sclerosing cemental masses of the jaw, florid osseous dysplasia, Ewing's sarcoma, osteosarcoma, and metastasis, as well as the lack of pathognomonic features, signify that the diagnosis of this disease should be established by a combination of clinical, radiographic, and histologic findings.

VIEW IMAGE

FIGURE 17-77 Tuberculosis osteomyelitis. Pantomogram shows ill-defined borders and formation of sequestra (*arrowheads*).

Osteoradionecrosis

Osteoradionecrosis is a pathologic process that sometimes follows heavy irradiation of bone and is characterized by a chronic, painful necrosis accompanied by late sequestration and sometimes permanent deformity.[180, 181] The radiation effects are endothelial cell death, hyalinization resulting from amyloid degeneration, and thrombosis of vessels. The periosteum undergoes fibrosis, and bone osteocytes and osteoblasts become necrotic, with fibrosis of the marrow spaces. Bone trabeculae are reduced in width and number, so that there is an increase in the size of the marrow spaces, which contain necrotic debris. These changes are progressive and lead to necrosis of bone and sequestration, although there is no clear line of demarcation between vital and nonvital bones. Radiologically, the bone can be normal in the early stages. The progression of the bone change is slow and slight. In advanced cases, there are multiple radiolucent areas with poorly defined borders and enlarged, irregular trabecular spaces (with the typical moth-eaten appearance) containing areas of sequestra (Fig. 17-79).

SECTION TWO

SYSTEMATIC APPROACH TO IMAGING DIAGNOSIS OF JAW LESIONS

Takashi Kaneda, Manabu Minami, Hugh D. Curtin, Mitsuaki Yamashiro, Yoshiaki Akimoto, Kuni Ohtomo, Hiroyuki Okada, and Hirotsugu Yamamoto

The objective of this section is to present a systematic approach to the diagnosis of jaw lesions using various imaging findings.

Odontogenic tumors comprise about 10% of all tumors of the oral cavity and about 2.4% of all lesions biopsied by dentists in the United States.[3, 182] After clinical examination, the patient with a suspected jaw lesion is first referred for plain radiography, pantomogram, or sometimes CT. The radiologic examination is part of the overall diagnostic process. Oral surgeons need a differential diagnosis of the disease as well as an exact assessment of the topography and extent of the lesion. Infiltration into surrounding tissues must also be evaluated.

Radiologic diagnosis of jawbone lesions has used conventional radiography including dental and occlusal films, pantomography, conventional tomography, and CT.[183–185] More recently, MR imaging has allowed excellent soft-tissue differentiation, and its increasing application is beginning to have an impact on the diagnosis of dento-maxillofacial lesions.[186–190]

As discussed in the previous section, few radiographic or imaging appearances are pathognomonic for a specific lesion. Based on all imaging modalities, the disease pattern may indicate several different diseases of either odontogenic or nonodontogenic origin. The question is, ''How do we use the imaging modalities to differentiate these jawbone lesions?'' What is needed is an effective, systematic approach to solve this problem.

Conventional radiography and pantomography provide screening imaging in various pathologic conditions of the maxilla and mandible and may suggest the need for further radiologic examinations such as CT or MR imaging. Imaging in at least two planes is necessary to analyze the lesion and adjacent tissues properly. Currently, multidetector CT provides images in multiple planes from a single spiral scan acquisition. Dental reformatting software also provides cross-sectional as well as panoramic sectional imaging.

When a jaw lesion is first identified, inflammation related to a tooth is usually considered first because of the high incidence of caries and related periapical disease. Inflammation can progress and lead to several different pathologic

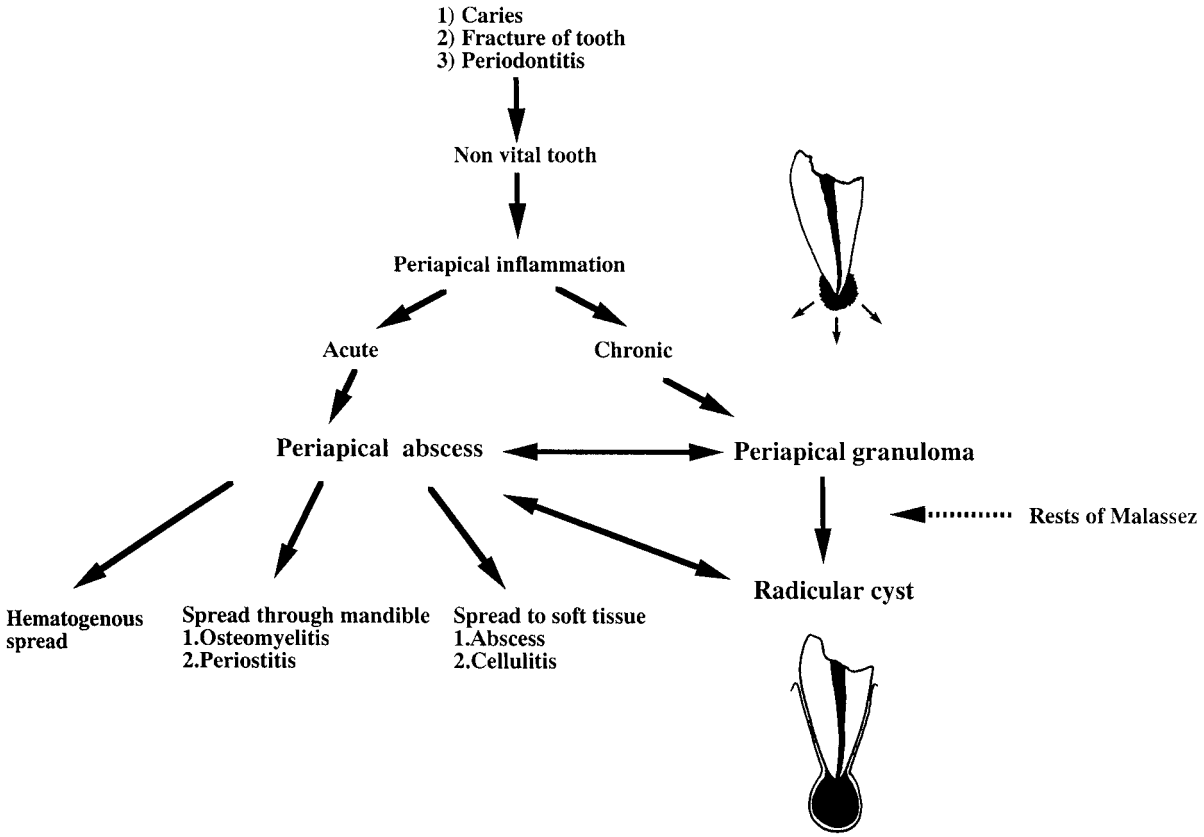

FIGURE 17-80 Sequelae of tooth infection.

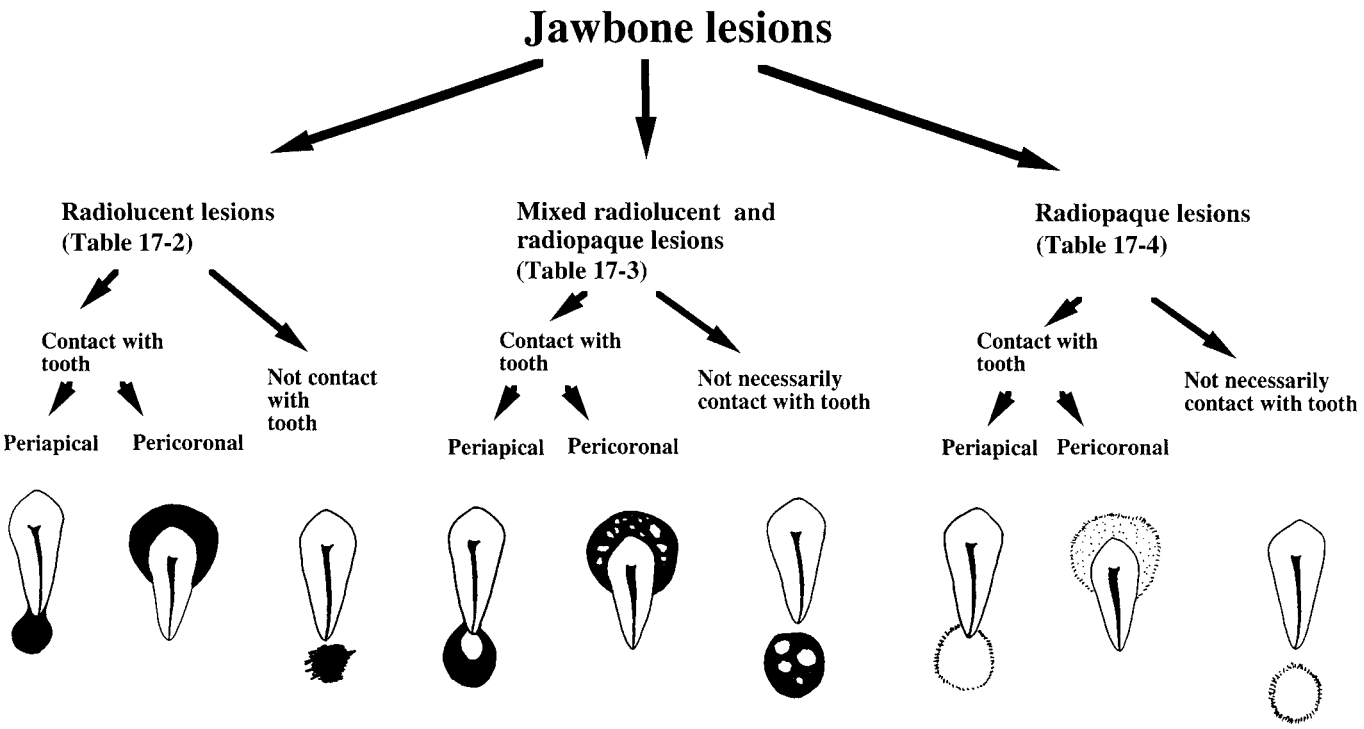

FIGURE 17-81 Systematic approach using radiologic examination of jawbone lesions.

VIEW IMAGE

conditions including periapical inflammation, periapical granuloma, periapical abscess, and radicular cyst (Fig. 17-80). Specifically, periapical inflammation or periapical granuloma is initiated and maintained by degeneration products of necrotic pulp tissue of a nonvital tooth. Stimulation of the resident epithelial rests of Malassez occurs in response to the products of inflammation. When the infection reaches the periapical tissue, many different tissue reactions may occur, depending on the nature of the infection and the resistance of the host.

If an inflammatory pathology can be excluded as a potential diagnosis, then the various tumors and cysts must be considered.

As previously discussed, the radiologic analysis for differential diagnosis primarily depends on changes in density, character of the margin, location, relationship to the teeth (including root resorption), and other radiologic findings (Fig. 17-81). The lesion may have a radiolucent, radiopaque, or mixed appearance. The margin may be sharp or indistinct, sclerotic or well corticated. Other useful radiologic findings are (1) the degree of extension, (2) the internal architecture of the lesion, (3) changes in the cortex of the mandible, and (4) periosteal reactions and soft-tissue changes. The relationship to a particular part of a tooth is extremely useful in the diagnosis of jaw lesions.[1, 191, 192]

RADIOLUCENT LESIONS

Well-Defined Radiolucent Lesions

Maxillomandibular lesions most frequently show a unilocular pattern or a multilocular pattern with internal septa.[1, 191, 192] A number of odontogenic and nonodontogenic lesions including periapical lesions, cyst of the globullomaxillary region, dentigerous cyst, primodial cyst, OKC, and ameloblastoma can present as well-defined radiolucent lesions (Table 17-2). When the lesion is equal or less than 2 cm in diameter, most of the lesions can be well evaluated by radiography alone. When radiolucent lesions are more than 2 cm in diameter, addition of MR imaging can be useful, especially for the evaluation of internal structures and the nature of the content, as stated below.[193]

Ill-Defined Radiolucent Lesions

Ill-defined radiolucent lesions are produced by inflammation and by malignancies of the jaw including carcinoma and osteosarcoma. Most carcinomas involving the jaws are invading from the lesions of the oral mucosa. Some may be metastatic deposits from primary tumors in distant sites.[185, 191, 192]

MIXED RADIOLUCENT-RADIOPAQUE LESIONS

A mixed radiolucent-radiopaque appearance (Table 17-3) can result from the presence of two or more tissues with different radiographic densities, varying degrees of maturation of the inflammatory soft tissue within the lesion, and localized resorption and apposition of new bone within or around the lesion. This appearance may indicate osteomyelitis, an immature fibroosseous lesion, or tumor.[185, 191, 192] The location of the lesion sometimes gives the clue for differentiation, but is not always a definite differential point.

RADIOPAQUE LESIONS

Radiopacity in the jawbones is produced mainly by osteosclerosis, thickening of the cortex, cemental masses, or impacted teeth. Radiopaque lesions in the maxillomandibular region are usually fibroosseous lesions, inflammation, or tumors.[185, 191, 192] These lesions are considered to be best differentiated by a combination of plain radiography and high-resolution CT (Table 17-4).

MR IMAGING

MR imaging (Fig. 17-82) has an advantage over plain films and CT in that it directly visualizes bone marrow characteristics, is more sensitive to contrast enhancement, better evaluates soft-tissue involvement, and provides multiple planes of imaging without radiation. MR imaging is said to be less useful in examining cortical bone because of the lack of signal generated by compact bone. However, invading tumors involving the cortex can be identified, as the intermediate signal of the tumor replaces the signal void usually seen in the cortex. MR imaging is less frequently affected than CT by artifacts related to dental materials, but the images can be seriously distorted by dental materials with high ferrous content. Artifacts related to dental materials on MR imaging are mainly dependent on the strength of the magnetic field, the specific pulse sequence and scan direction, and the nature of the dental materials. In addition, some injury to the gingiva is unavoidable at dental treatment and subsequent implantation of dental bur

fragments into the gingiva may occur, resulting in local image distortion.[194]

MR imaging has been reported to be superior to CT in the evaluation of certain characteristics of apparently cystic lesions, giving better information about the inner consistency of the lesion with demonstration of cystic or solid components, thickness of cyst walls, and heterogeneity of fluid content. For example, an OKC frequently shows heterogeneous intensity of fluid contents on MR imaging, while other types of cysts usually show more homogeneous fluid intensity. Some cysts, especially inflammatory cysts, can be misdiagnosed as having a mixed or solid pattern on noncontrast studies and require contrast-enhanced examinations for accurate diagnosis.[190] These findings can be most easily evaluated in lesions larger than 2 cm in diameter.

MR imaging is also useful in differentiating ameloblastoma from larger cysts by demonstrating thick walls and papillary projections, especially on contrast examinations.[188] Other types of maxillomandibular benign tumors show well-defined solid components and some enhancement on contrast-enhanced T1-weighted images, but these findings are usually less helpful in separating various diagnoses. Maxillomandibular malignant tumors show ill-defined inhomogeneous enhancement on gadolinium-enhanced T1-weighted images. The findings are nonspecific but are useful in the evaluation of tumor extension for preoperative planning.

With osseous lesions in the maxillomandibular region, conventional tomography and CT are superior to MR imaging because of their better detection of calcification and cortical abnormality.

SECTION THREE

DENTAL ANOMALIES AND SYSTEMIC DISEASE

Jorge Bianchi and Hugh D. Curtin

The purpose of this section is not to provide a complete description of every dental anomaly with a correlating imaging appearance or to discuss extensively the various manifestations of systemic disease. Rather, its purpose is to describe those conditions that may be seen incidentally during imaging of the head and neck and that may be questioned during interpretation of an examination done for an unrelated reason. It is hoped that some of the terminology will prove useful to the reader. A systemic disease will usually be obvious by the time the patient comes to imaging. Almost all of the dental anomalies described here are best shown by plain dental radiographs.

DENTAL ANOMALIES

Dental anomalies include variations in the shape, size, number, and morphology of the teeth. These types of abnormalities are relatively frequent and are usually diagnosed by the general dentist with plain radiographic films. Although most anomalies occur as isolated entities, some are associated with extraoral abnormalities. The various tooth structures (enamel, dentin, cementum, and periodontal ligament) have different embryologic origins, and abnormalities affecting a particular tooth structure may be associated with disorders of extradental tissues that have a similar embryologic origin.

Supernumerary Teeth

Supernumerary teeth are simply extra teeth (Fig. 17-83). They occur mainly in the anterior region of the maxilla. A supernumerary tooth in the anterior maxilla is called a mesiodens.[195] An extra tooth seen posterior to the molar area is called a distomolar or distodent. The term *paramolar* has been used to describe a supernumerary tooth in the region of the molars. It can be lingual (medial), buccal (lateral), or occur between the normal molars. The term has been used to describe a distomolar as well. Supernumerary teeth are usually smaller than normal teeth and are more common in the permanent dentition. They are present in 1% to 4% of the population.[196] Syndromes associated with supernumerary teeth include Gardner's syndrome and cleidocranial dysplasia, but a supernumerary tooth is most commonly seen as an isolated phenomenon.[197]

The presence of supernumerary teeth may affect the normal eruption of teeth and therefore future appropriate positioning of the teeth. Thus, the dentist may want to know the position and orientation of the mesiodens in the maxilla or jaw, as the position, orientation, and inclination of the mesiodens can be significant in potential treatment.

Palatal orientation refers to the position of the tooth facing the hard palate. Buccal orientation refers to the position of the tooth facing the cheek and the buccal mucosa of the alveolar process. The dentist can plan extractions or orthodontic treatment (teeth alignment) knowing the position and orientation of the mesiodens. Distomolars or paramolars may also have different inclinations and positions that can affect normal occlusion.

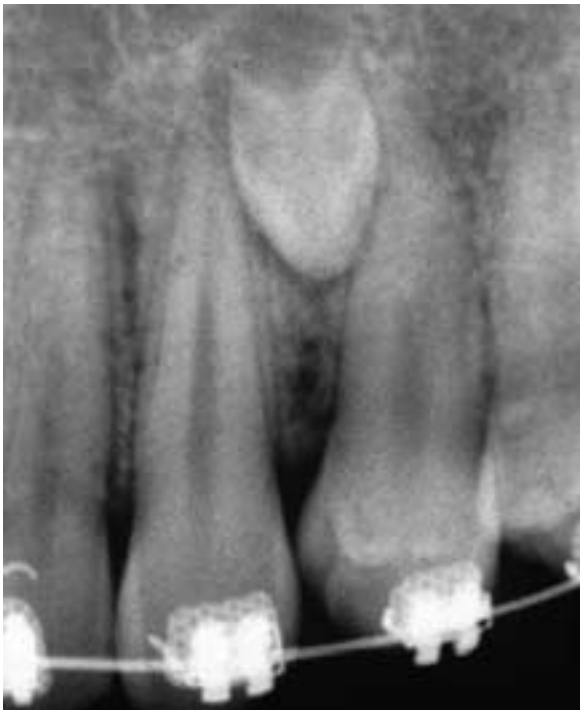

FIGURE 17-83 Supernumerary tooth. Periapical view of the anterior maxilla shows a supernumerary tooth between the left canine and first premolar.

VIEW IMAGE

Hypodontia

Hypodontia is the absence of one or more teeth.[198] This condition occurs in permanent dentition in 5% to 10% of the population. The most common missing teeth excluding the third molars are the mandibular second premolars and maxillary lateral incisors, respectively.[198, 199] Disorders associated with missing teeth include ectodermal dysplasia, epidermolysis bullosa, and a variety of other disorders.[200]

Ectodermal dysplasia is an X-linked recessive disorder characterized by the absence or deficient development of at least two derivatives of the ectoderm such as the teeth, hair, and nails (Fig. 17-84). Charles Darwin identified the first case in the 1860s.

Epidermolysis bullosa is a rare genetic disorder characterized by blister formation on the mucosa or skin that develops in response to minor trauma.

Radiation treatment can affect the normal development of the teeth, and missing teeth is a common consequence of radiation therapy in children.

Macrodontia and Microdontia

Macrodontia and microdontia refer to correlations between the size of a tooth and its correspondent on the opposite side of the arch.[199–201] Teeth may be bigger or smaller (Fig. 17-85) in a normal healthy individual. However, macrodontia and microdontia can affect the space available in the jaws for the teeth and therefore can affect normal occlusion. This may lead to misalignment of the teeth in the arch.

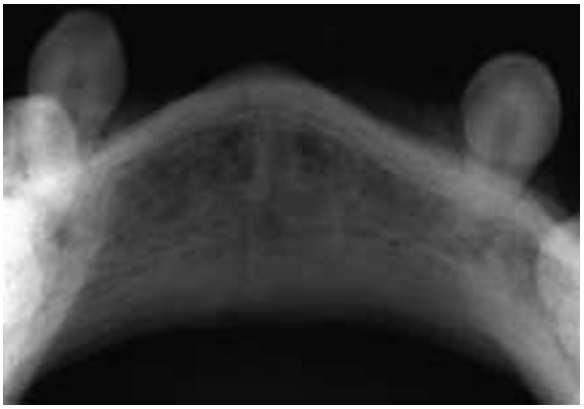

FIGURE 17-84 Ectodermal dysplasia. Occlusal view. Abnormal teeth with absence of central incisors.

Dens in Dente (Dens Invaginatus)

Dens in dente results from an invagination of the outer surface of the tooth into the inner part of the tooth (Figs. 17-86 and 17-87).[202, 203] It occurs most frequently in permanent upper lateral incisors. It can occur in any region of the tooth but usually affects the crown of the tooth, with the enamel folding inward. The vitality of the tooth may be compromised. When the abnormality involves the root of the tooth, the defect is lined by cementum.[202, 203]

Pulp Stones

Pulp stones are calcifications in the pulp chamber of the tooth (Figs. 17-88 and 17-89). The etiology is unclear, but there may be a direct relationship with increased age. The molar teeth are most commonly affected, but pulp stones can affect any tooth. At clinical inspection, a tooth with a pulp stone looks like any other tooth. A pulp stone may make root canal treatment difficult or impossible. Pulp calcifications have been found in association with tumoral calcinosis, dentin dysplasia, and Ehlers-Danlos syndrome.[204]

Enamel Pearls

Enamel pearls are small spherical enamel masses located at the root of the molars and are found in 2% of the population (Figs. 17-90 and 17-91).[205] There can be a small pulp chamber extending from the parent tooth. Enamel pearls can distort the periodontal space and may predispose the patient to periodontal disease, but usually they are not considered to have clinical significance. Occurring beneath the gingiva, they are not usually clinically obvious.

Amelogenesis Imperfecta

Normal enamel is the densest material in the human body. Enamel covers the outer surface of the teeth and is almost 100% inorganic, composed mainly of hydroxyapatite crystals. Its attenuation value at CT is 3000 HU. Amelogenesis imperfecta is a developmental disorder that involves generalized abnormal enamel formation.[3] Strong autosomal and recessive X-linked associations have been documented.[206] The enamel is very thin (Fig. 17-92). The dentin can be seen through the enamel, giving the tooth a darker or, in some cases, a yellow-brown color. Frequently the enamel will fracture easily and the teeth wear down quickly. In some

FIGURE 17-89 Periapical view of the right posterior mandible. The right permanent canine and first bicuspid show pulp stones in the pulp chamber (*arrows*).

FIGURE 17-90 Enamel pearls. Periapical view of the right posterior maxilla. Enamel pearls are seen in the cervical portion of the first and second permanent molars (*arrows*).

variants the teeth readily absorb stains, adding a darkened component to the already abnormal appearance.[207]

The radiographic appearance varies with the subtype.[3, 207, 208] The enamel may be of normal density but very thin (hypoplastic form). The thickness initially may be relatively normal but the density is low, at times even lower than the radiographic appearance of dentin (hypomaturation or hypocalcified form). All forms erode or wear easily and the enamel may be worn down, giving a squared-off appearance to the crown.

Dentinogenesis Imperfecta

Dentinogenesis imperfecta (DI) is an autosomal dominant developmental disturbance of dentin formation.[209] Dentin is the inner layer of the tooth structure and has a more organic matrix than the enamel. DI can affect both primary

FIGURE 17-92 Amelogenesis imperfecta. Periapical view of the anterior maxilla. Dentin, pulp chamber, and cementum are present, but there is no or very thin enamel (*arrows*).

FIGURE 17-93 DI. Periapical view of the right maxilla shows pulp chamber obliteration and short teeth consistent with DI. An impacted canine is also seen.

VIEW IMAGE

and secondary dentitions and has no sex predilection. It may be associated with osteogenesis imperfecta but can occur in isolation, without associated skeletal abnormalities.[210] The term *hereditary opalescent dentin* has been applied to the isolated defect variant. The teeth may be translucent and vary in color from yellow to gray. The enamel fractures easily, and the teeth wear readily.[210]

Radiographic features of DI can include a variety of abnormalities. There can be a constriction of the cervical portion of the tooth (junction between enamel and cementum). The roots can be narrowed or short. There can be partial or complete obliteration of the pulp chamber (Fig. 17-93). The lucency is replaced by an opacity that is more characteristic of dentin.

Taurodontia

Taurodontia or taurodontism is an inherited anomaly characterized by enlarged pulp chambers of the teeth (Fig. 17-94). The pulp chamber's size is increased. Clinically, teeth with taurodontia appear no different than normal teeth. The radiographic identification of taurodonia is important because of the risk of exposing the pulp chamber during dental procedures.

Dentin Dysplasias

Dentin dysplasia is a rare dental anomaly. It is an autosomal dominant condition characterized by abnormal tooth and root formation.[211] Dentin dysplasias have two variants. Dentin dysplasia type 1 (radicular type) is characterized by poorly developed roots (chopped roots) and obliterated pulp chambers. The crown of the tooth may have normal color or may be slightly darker than normal. Radiologically, obliteration of the pulp cavity is present at birth. In dentin dysplasia type 2 (coronal type), the tooth has the same appearance as in DI. Clinically, the tooth is translucent. Radiography shows narrowing or obliteration of the pulp chamber occurs. Obliteration of the pulp chamber occurs later in dentin dysplasia than in DI. Dentin dysplasia is an uncommon condition.[211]

DENTAL MANIFESTATION OF METABOLIC AND SYSTEMIC CONDITIONS

A number of metabolic diseases that affect bone biology can also affect the teeth and surrounding structures including the bone, the lamina dura, and the periodontal ligament. Conditions such as hyperparathyroidism, osteoporosis, renal osteodystrophy, and rickets may lead to altered trabeculation of bone, loss or thinning of lamina dura, and a ''ground glass'' appearance of bone. The dentist may identify this radiographic sign during a regular plain film examination.

FIGURE 17-94 Taurodontia. Periapical views of the left and right posterior mandibles. Enlarged pulp chambers are noted.

Systemic conditions such as scleroderma (progressive systemic sclerosis) can present with generalized enlargement of the periodontal ligament (PDL) space.[212–214] The precise explanation of the finding is not known, but the abnormality has been attributed to an obliterative microvascuopathy and a thickened periodontal membrane.[212] The reduction in vascularity of the PDL space may predispose the patient to superimposed periodontal disease as well. This finding is not universal in patients with scleroderma. The differential diagnosis of enlarged PDL space includes occlusal trauma, orthodontic braces (alignment device), and malignancies. Orthodontic appliances pulling on the tooth will usually enlarge one aspect of the PDL space at the expense of the opposite side. The PDL space is narrowed on the side to which the tooth is being ''pulled.'' Malignancies in the jaws such as leukemia, lymphomas, sarcomas, primary lesions, or metastasis may present with teeth ''floating in space,'' localized alveolar bone destruction, and enlarged PDL spaces. ''Floating teeth'' are also seen in histiocytosis.

Patients with scleroderma can have bone changes as well, and there can be pronounced erosions at points of muscle attachment. Erosions or scalloping of the bone can be seen in the area of the angle of the mandible or more anteriorly where the anterior belly of the digastric attaches to the mandible. There can also be involvement of the coronoid process or condyle.

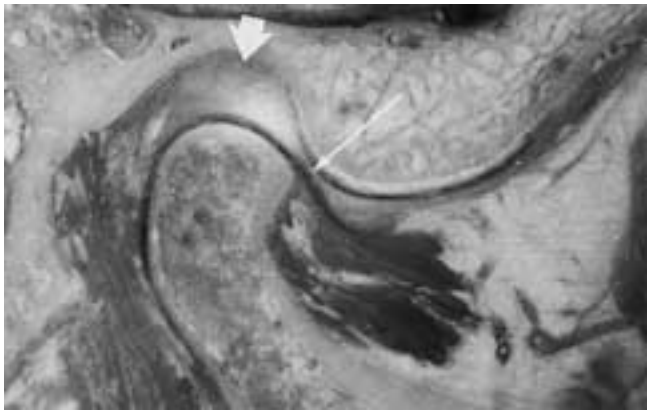
The purpose of an imaging assessment of the temporomandibular joint (TMJ) is to graphically depict clinically suspected disorders of the joint. For many years, plain film radiography done mainly in a transcranial projection was the most commonly used method of making this assessment. This modality has major limitations because it is sensitive only to changes in the osseous components and depicts just the lateral aspect of the joint. With the evolution of newer imaging modalities such as arthrography, computed tomography (CT), and, most importantly, magnetic resonance (MR) imaging, the soft tissues of the joint could be appreciated. This allowed a better understanding of the anatomy and pathophysiology of internal derangements related to disk displacement.[1]

This chapter begins with descriptions of the anatomy and function of the TMJ and then provides an overview of the various imaging modalities available for evaluating the TMJ. Because most TMJ imaging is directed toward assessment of internal derangements or related degenerative joint changes, the sections addressing imaging methods emphasize the key findings in these important disorders. A variety of miscellaneous diseases that affect the TMJ are then covered, and an algorithm for imaging patients with TMJ problems is given.

ANATOMY OF THE TMJ

Interpreting TMJ imaging studies requires an understanding of the pathophysiology of the joint and a knowledge of both normal and pathologic anatomy of the joint and surrounding structures. Therefore, a description of joint anatomy, joint pathology, function, and dysfunction is presented in some detail.

The mandible and the temporal bone comprise the osseous components of the TMJ. The head of the mandibular condyle comprises the inferior component of the joint, and the temporal bone contributes the glenoid fossa and articular tubercle, forming the superior osseous (or skull base) part of the joint (Fig. 18-1). Unlike most other joints of the body, which have cartilaginous coverings, the articulating surfaces



VIEW IMAGE

FIGURE 18-1 Normal TMJ in sagittal section. Biconcave disk in the normal superior position. The posterior band of the disk (*thick arrow*) is lying over the condyle. The central thin zone of the disk (*thin arrow*) is between the anterior prominence of the condyle and the articular eminence.

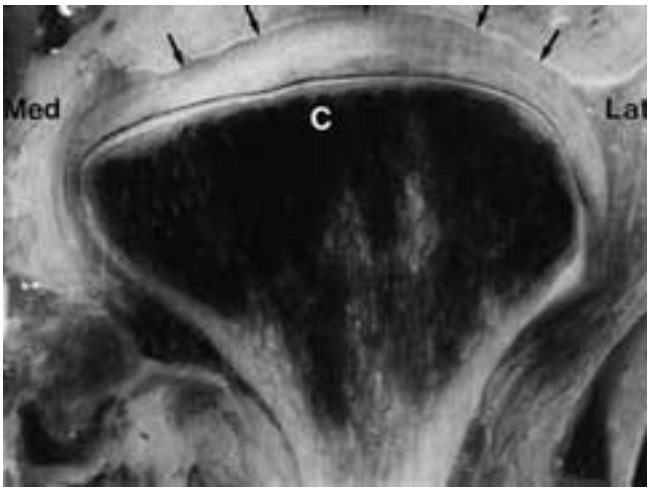


FIGURE 18-2 Normal TMJ in coronal section. The disk (*arrows*) is crescent-shaped and located over the condyle. Medially and laterally, the disk is attached to the condyle and capsule. The condyle (*C*) is indicated.

VIEW IMAGE

of the TMJ are covered by a thin layer of dense fibrous tissue.

The TMJ disk is a biconcave fibrous structure located between the mandibular condyle and the temporal component of the joint. The disk is round to oval, with a thick periphery and a thin central part. The mediolateral dimension of the disk is approximately 20 mm. In a sagittal section the normal disk appears biconcave, with the anterior and posterior thicker parts of the disk, respectively, referred to as the anterior and posterior bands.[2] In the normal joint the posterior band is located over the condyle, and the central thin zone is located between the condyle and the posterior part of the articular tubercle (Fig. 18-1). The anterior band is located under the articular tubercle. In the coronal plane, a section through the disk is crescent-shaped (Fig. 18-2). A joint capsule surrounds the joint, emerging from the temporal bone and extending like a funnel inferiorly to attach to the neck of the condyle. The medial and lateral edges of the disk attach to the capsule and then to the mandible at the inferior edge of the medial and lateral poles of the condyle (Fig. 18-2). Posteriorly, the disk is attached to the temporal bone and to the condyle by the posterior disk attachment. This attachment is extremely important in internal derangements of the TMJ. This region has also been referred to as the bilaminar zone or the retrodiskal tissue. The structure consists of loose fibrous connective and elastic tissue components. The posterior disk attachment has traditionally been called the bilaminar zone because initial histologic studies indicated that the upper part was elastic tissue and the lower part consisted of more connective tissue. However, more recent histologic studies have failed to confirm the bilaminar nature of the posterior disk attachment. Despite this, the term *bilaminar zone* continues to be used in both clinical and scientific work. The bilaminar zone also contains many small blood vessels. Anteriorly, the disk is attached to the joint capsule, and in the anteromedial portion of the joint the disk also merges with the upper head of the lateral pterygoid muscle.

There are two joint spaces, or compartments. The superior space separates the glenoid and articular eminence

of the temporal bone from the disk and its attachments. The inferior joint space separates the disk and its attachments from the condyle of the mandible. The anterior recess is a small space in the inferior joint compartment anterior to the condyle. The posterior recess is the part of the inferior joint space posterior to the condyle. The lower part of the bilaminar zone (posterior disk attachment) curves downward to attach to the condylar neck and thus forms the posterior boundary of the posterior recess of the inferior joint compartment.

FUNCTION OF THE TMJ

The function of the TMJ is complex because the upper and lower joint compartments principally act as two small joints within this same joint capsule. This allows for proportionally greater movement of the TMJ in relation to the actual size of the joint. The principal function of the disk is to permit relatively large movements within a small joint while maintaining stability. Rotation and translation occur in both the upper and lower joint spaces. However, translation occurs predominantly in the upper space, and rotation is more evident in the lower joint space. In the initial phase of jaw opening, the condyle rotates in the lower joint compartment. After this initial rotation, translation occurs in the upper and subsequently in the lower joint space. During translation, the condyle and the disk translate (slide) together under the articular tubercle. During all mandibular movements, the central thin part of the disk is located between the condyle and the articular tubercle. This suggests that the thick periphery of the disk and the thick posterior and anterior bands act as functional guides for the joint. This normal joint function can be identified in anatomic specimens of the TMJ (Fig. 18-3).

INTERNAL DERANGEMENT RELATED TO DISPLACEMENT OF THE DISK

Internal derangement is a general orthopedic term implying a mechanical fault that interferes with the smooth action of a joint.[3] Internal derangement is thus a functional diagnosis, and for the TMJ the most common internal derangement is displacement of the disk.[4–9] Most often the disk displaces in an anterior, anterolateral, or anteromedial direction. Thus the posterior band of the disk prolapses anteriorly, relative to the superior surface of the condyle (Figs. 18-4 and 18-5), instead of remaining in position between the condyle and glenoid fossa. As a consequence, the condyle is positioned under the posterior disk attachment rather than under the disk, and the condyle closes on the posterior attachment (bilaminar zone or retrodiskal tissues) rather than on the disk itself. The central thin part of the disk lies inferior to the articular tubercle.

Studies have shown that the disk frequently is also displaced in a medial (Fig. 18-6) or lateral direction.[10–13] Posterior disk displacement (Fig. 18-7) does occur, but it is rare. When present, it is frequently seen in combination with

medial disk displacement. A general classification of the different types of disk displacement of the TMJ is shown in Box 18-1. Pure lateral and pure medial sideways displacements of the disk also occur, but not as commonly as in combination with anterior displacement.[11–13] The combination of anterior and lateral or medial displacement is called rotational displacement, whereas pure lateral or pure medial displacement is called sideways displacement.[11]

The functional aspects of disk displacement include displacement with or without reduction. The functional categories of internal derangement are illustrated in Figure 18-8. In disk displacement with reduction (Fig. 18-8B) the disk is anteriorly displaced in the closed-mouth position but reverts to a normal superior position during opening. In disk displacement without reduction (Fig. 18-8C) the disk lies anterior to the condyle during all mandibular movements, and the normal condyle–disk relationship is not reestablished.

Disk Displacement with Reduction

When a displaced disk reduces to a normal position, a click is usually heard. When the jaw closes, the disk again

displaces anteriorly, usually during the last phase of the closing movement of the jaw, and again a click is commonly heard. The closing click usually is less prominent than the opening click. The cyclic nature of disk displacement was described by Ireland in 1951.[14] The clicking sound has been shown to be caused by the impact of the condyle hitting the temporal bone component of the articulation after the condyle has passed under the posterior band of the disk.[15, 16]

Disk Displacement without Reduction

In disk displacement without reduction (Fig. 18-8C) the disk remains displaced relative to the condylar head, regardless of the jaw position. In the initial stages of this condition, jaw opening is typically limited and the jaw deviates to the side of the affected joint. However, this clinical characteristic is typical only during the initial (early) phase; with time, the opening capacity of the TMJ increases and the jaw no longer deviates to the affected side. This is the result of stretching or progressive elongation of the posterior disk attachment and, to a lesser extent, deformation of the disk itself. In the early stage, disk displacement without reduction is usually not associated with joint sounds.

Disk Deformity

The normal disk is biconcave when viewed in the sagittal plane (Fig. 18-3). In the early stages of internal derangement the disk remains normal in shape. However, the displaced disk begins to deform, as noted by thickening of the posterior band and shortening of the entire anteroposterior length of the disk (Fig. 18-9).[4, 9, 17–19] Additionally, both the central thin part and the anterior band decrease in size. The end result is a biconvex disk configuration and a stretched, elongated, and thinned posterior disk attachment. The gross changes of the disk are associated with histologic alterations within the disk that lead to metaplastic hyaline cartilage, hyalinization, and accumulation of foci of calcium deposits and abnormal collagen patterns.[20, 21] Changes also occur in the posterior disk attachment itself, leading to fibrosis and narrowing of vessels.[22, 23] Histologic studies of the posterior disk attachment in joints with disk displacement have shown narrowing of the arterial lumen, increased density of fibroblasts, and hyalinization of loose connective tissue.[24]

Late-Stage Changes Following Disk Displacement

In the late or chronic stages of disk displacement without reduction, the disk is deformed and has a stretched, torn, or detached posterior attachment; communications between the upper and lower joint spaces (perforation) are often seen.[8, 9, 19, 25] Most commonly the perforations are found in the posterior disk attachment, at its junction with the disk itself (Fig. 18-10). Infrequently, perforations are found in the disk per se.[19] Thus, although traditionally this condition has been designated *perforation of the disk*, this is not anatomically correct, as the perforations are usually found in the posterior disk attachment rather than in the disk proper.

Osseous changes involving the condyle and temporal

FIGURE 18-9 Anterior displacement and deformation of the disk. The disk (*arrow*) is biconvex. The condyle (*C*) articulates with the posterior disk attachment.

bone often occur as sequelae of disk displacement.[7-9, 18, 26] Osseous changes consist of flattening and osteophytosis of the mandibular condyle and flattening of the temporal component of the articulation. These changes are more commonly observed in the lateral part of the joint and can be detected on plain film imaging. It should be noted that osseous changes are relatively late findings in the disease process, and it is often difficult to differentiate radiographically between advanced remodeling and degenerative joint disease.

Clinical Aspects of Internal Derangement

The preceding classification of disk position and function is based only on anatomic and functional aspects. In the clinical setting the patient's history, signs, and symptoms must be incorporated into the staging of the disease. Patients may complain of pain or of clicks when opening and closing the mouth. Physical examination may show tenderness on palpation of the joint or associated muscles. Palpable clicks or crepitus on movement of the jaw may be clinically evident, and abnormalities of occlusion or deviation of the jaw on opening may also suggest TMJ abnormality.

However, the clinical assessment of the TMJ has definite limitations. Multiple studies have shown that the accuracy of the physical examination in predicting the status of the joint is about 70%.[27–33] The intensity and location of pain in a study of more than 200 patients did not distinguish patients with internal derangement from those without internal derangement, and there was no consistent relationship between occlusion and the status of the joint. These studies indicate that physical examination alone is not reliable in determining the status of the joint.[28–34]

The situation is further complicated by the fact that clinical signs of TMJ internal derangement are relatively common in the general population. An epidemiologic study of more than 400 individuals ranging in age from 28 to 73 years showed clinical evidence of internal derangement in 39%. Most of these individuals had functional symptoms with clicking or limitation of opening, but the majority did not have any pain associated with the dysfunction. Studies of asymptomatic volunteers using both arthrography and MR imaging have shown disk displacement in approximately 20% to 25% of this population.[35–37] The finding of anatomic abnormalities in the joints of asymptomatic individuals is not unique to the TMJ. Similar observations have been shown in MR studies of the knee, cervical spine, and lumbar spine.[38–42]

The prevalence of disk displacement in symptomatic individuals is much higher than in a normal population.[43] In view of the high incidence of displacement in asymptomatic patients, the precise relationship of symptoms to the displacement is difficult to define. Disk displacement has been found in approximately 80% of patients with symptoms of TMD referred for MR imaging.[44] Several forms of disk displacement have been demonstrated in up to one third of asymptomatic volunteers.[44–46] One study analyzing the type of disk displacement in patients and asymptomatic volunteers showed that most of the volunteers have early stage disk displacement, and more severe displacements are seen in symptomatic patients.[47] However, complete disk dislocations are found incidentally in patients without complaints referable to the TMJ. Perhaps further investigation of these apparently asymptomatic patients could determine some degree of joint dysfunction, but clearly more work is necessary before the precise relationship between disk position and pain can be confidently defined.

Among patients presenting with TMJ symptoms, there is a significant prevalence of young females, and in the clinical population the female/male ratio has been between 5∶1 and 10∶1. The reason for the female dominance among TMJ patients is not fully understood. Cadaver studies have found that approximately 50% of elderly individuals have an internal derangement, with no significant difference between the sexes.[48]

Because of the difficulty in the clinical evaluation of a potential disk displacement, imaging must be done to define the anatomy of the joint and to determine the relationship of the disk to the condyle. The purpose of an imaging study is to identify and characterize the anatomy in a patient who presents with symptoms. Because of the overlap of morphologic abnormalities in symptomatic and asymptomatic individuals, imaging findings should always be interpreted in light of clinical findings. Similarly, the choice of imaging studies must depend on the clinical evaluation, and an algorithm for TMJ imaging can be made based upon prior clinical and imaging experience.

An appropriate patient evaluation integrates the imaging and clinical findings. A workable classification of TMJ disorders, related to internal derangement, is also necessary for communication among clinicians and radiologists. The classification developed by Wilkes[9] encompasses clinical, radiographic, and morphologic observations and categorizes internal derangement into early, intermediate, and late stages. This classification is presented in Box 18-2.

IMAGING

Transcranial and Transmaxillary Projections

BOX 18-2

CLASSIFICATION OF INTERNAL DERANGEMENT

Early Stage	
Clinical	No significant mechanical symptoms other than reciprocal clicking (early in opening movement, late in closing movement, and soft in intensity); no pain or limitation in opening motion
Radiologic	Slight forward displacement; good anatomic contour of disk; normal tomograms
Surgical	Normal anatomic form; slight anterior displacement; passive incoordination (clicking) demonstrable
Early-Intermediate Stage	
Clinical	First few episodes of pain; occasional joint tenderness and related temporal headaches; beginning of major mechanical problems; increase in intensity of clicking sounds; joint sounds later in opening movement; and beginning transient subluxations or joint catching and locking
Radiologic	Slight forward displacement; slight thickening of posterior edge or beginning of anatomic deformity of disk; normal tomograms
Surgical	Anterior displacement; early anatomic deformity (slight to mild thickening of posterior edge); well-defined central articulating area
Intermediate Stage	
Clinical	Multiple episodes of pain, joint tenderness, temporal headaches, major mechanical symptoms: transient catching, locking, and sustained locking (closed locks); restriction of motion; difficulty (pain) with function
Radiologic	Anterior displacement with significant anatomic deformity or prolapse of disk (moderate to marked thickening of posterior edge); normal tomograms
Surgical	Marked anatomic deformity with displacement; variable adhesions (anterior, lateral, and posterior recesses); no hard-tissue changes
Intermediate-Late Stage	
Clinical	Characterized by chronicity with variable and episodic pain, headaches, variable restriction of motion; undulating course
Radiologic	Increase in severity over intermediate stage; abnormal tomograms; early to moderate degenerative remodeling; hard-tissue changes
Surgical	Increase in severity over intermediate stage; hard-tissue degenerative remodeling changes of both bearing surfaces; osteophytic projections; multiple adhesions (lateral, anterior, and posterior recesses); no perforation of disk or attachment
Late Stage	
Clinical	Characterized by crepitus on examination; scraping, grating, grinding; variable and episodic pain; chronic restriction of motion; and difficulty with function
Radiologic	Anterior displacement; perforation with simultaneous filling of upper and lower compartments; filling defects; gross anatomic deformity of disk and hard tissues; abnormal tomograms; essentially degenerative arthritic changes
Surgical	Gross degenerative changes of disk and hard tissues; perforation of posterior attachments; erosions of bearing surfaces; multiple adhesions equivalent to degenerative arthritis (sclerosis, flattening, and anvil-shaped condyle, osteophytic projections, and subcortical cystic formation).

From Wilkes CH. Internal derangement of the TMJ. Pathologic variations. Arch Otolaryngol Head Neck Surg 1989;115:469-477.

projection (Fig. 18-11). The lateral aspect of the joint is well visualized, but the central and medial parts of the joint are not clearly seen because the x-ray beam is not tangent to these articular surfaces. This disadvantage is partly compensated for by the fact that most of the early osseous changes occur laterally in the joint.[49]

It has been recommended that, in addition to the transcranial projection, an anteroposterior projection should be used to depict the central and medial parts of the condyle. A transmaxillary projection (Fig. 18-12) or a transorbital projection also is suggested.[50]

Tomography

Complex motion tomography has been recommended for detection of early osseous changes (Fig. 18-13). Studies have demonstrated that a clearer depiction of the osseous anatomy can be gained from tomography than can be gained from transcranial radiography.[51] Tomography may also be performed in the coronal plane, providing information about the medial and lateral poles of the condyle, which are usually not adequately depicted on the sagittal tomograms. The disadvantage of tomography is the rather large radiation

Copyright © 2003, Mosby, Inc. All rights reserved.

dose delivered to the lens of the eye. To a large extent, tomography has been replaced by CT, which probably represents the most effective modality for demonstrating osseous abnormalities.

Arthrography

Development of TMJ Arthrography

Early attempts at TMJ arthrography were undertaken by Nørgaard in the 1940s.[52, 53] However, this procedure was not adopted by many clinicians. It was considered technically difficult and painful for the patient, and the information gathered was not considered of great value for treatment planning and evaluation of prognosis. Only a few descriptions of TMJ arthrography appeared in the literature over the ensuing 25 years.

Toward the end of the 1970s several articles appeared, describing the clinical and arthrographic characteristics of internal derangement related to displacement of the disk.[7, 8, 54–56] These arthrographic studies were actually the first to depict displacement of the disk, a pathologic entity that had been suspected earlier.[14, 57-61] During the following years, considerable enthusiasm developed for TMJ arthrography, and a large number of publications describing the usefulness of the technique appeared. The changed attitude toward TMJ arthrography can be traced to the following factors: (1) use of an image intensifier to facilitate joint puncture and to study and document joint dynamics, (2) identification of disk displacement as a common cause of TMJ pain and dysfunction, and, probably most important, (3) introduction of new, conservative surgical methods for treating disk displacement.[7, 8, 54, 55, 62–66] These newer treatment methods required accurate information about the status and function of the joint. The use of a nonionic contrast medium, which made the examination less painful, and the combination of arthrography and tomography, also influenced the increased use of arthrography.[6, 25]

Single- and Double-Contrast Arthrography

Injection of contrast medium into only the lower space (Fig. 18-14) is a simplification of the original arthrographic technique, in which contrast medium was injected into both upper and lower joint spaces.[5, 54, 55] This simplification

further popularized the use of arthrography; currently, single-contrast lower-compartment arthrography is the most commonly used arthrographic technique.[5, 54]

Double-contrast arthrography (Fig. 18-15) is a variant of arthrography in which injection of iodine contrast medium is combined with injection of air. [6, 17, 25, 56, 67, 68] The double-contrast study is superior to the single-contrast study in its demonstration of the configuration of the disk and the posterior disk attachment (Figs. 18-15 and 18-16). However, the double-contrast technique is technically more difficult to perform, because it requires cannulation of both the upper and lower joint spaces and the injection of both contrast medium and air.

Indications and Contraindications

MR imaging has almost completely replaced arthrography for establishing the position of the disk relative to the condyle, and many institutions have eliminated arthrography as a diagnostic procedure. Arthrography can still be done to assess the position and function of the disk in patients with pain and dysfunction suggesting internal derangement. Perforations of the disk or retrodiskal attachments can be identified as contrast injected into the inferior compartment passes freely into the superior compartment of the joint. Arthrography can be used in patients with TMJ disk displacement with reduction to determine the mandibular position that reestablishes a normal condyle–disk relationship.[54, 69] The purpose of this would be to establish the optimum position for initiating protrusive splint therapy (conservative therapy).[54, 69] Infrequently, arthrography is performed to delineate loose bodies within the joint spaces, for diagnostic aspiration of joint fluid, for intraarticular injection of cortisone, or for evaluation of the TMJ after trauma.

There are indications that arthrography occasionally relieves patients' symptoms.[70] Manipulation and lavage of the joint was shown to improve mobility and decrease pain in a small clinical study.[70] The mechanism is not fully understood, and the precise indications for therapeutic arthrography must await further studies.

An infrequent contraindication for TMJ arthrography is infection in the preauricular area, which could potentially result in contamination of the joint during the arthrographic procedure. In patients with previous reactions to contrast medium, other modalities such as MR imaging should be considered. However, arthrography has been performed on such patients without any premedication, and there was no untoward reaction. Bleeding disorders and anticoagulation medication also are relative contraindications to arthrography.

Radiologic Equipment and Procedure

A fluoroscopic table or a C-arm unit with an image intensifier is necessary equipment for this study. Because of the small size of the TMJ, it is also useful to be able to magnify the image to about three times its normal size. The capability for spot filming and videotape recording is valuable for documentation and the evaluation of joint dynamics. For double-contrast arthrography, tomography is also needed.

The examination is explained to the patient. The patient is placed on the tabletop in a laterally recumbent position, and the head is oriented so that the side to be injected faces up. The head is slightly tilted, and the transcranial projection is optimized with fluoroscopy. Opening and closing movements of the jaw, with attention to the condyle and fossa, are recorded on videotape before contrast medium is injected.

FIGURE 18-15 Dual space double-contrast arthrotomogram showing the disk (*arrow*) in a superior position. The mouth was half open, and the redundant posterior disk attachment (*arrowheads*) is seen between the disk and the posterior capsule. The upper and lower joint spaces are radiolucent due to the intraarticular injection of air.

VIEW IMAGE

Technique for Single-Contrast Arthrography

The superoposterior aspect of the condyle is clinically and fluoroscopically identified and indicated on the skin by a metal marker.[71] The area is marked with a pen, and a local anesthetic (1% to 2% lidocaine) is injected. The joint is punctured with a 23-gauge, 3/4 to 1 inch scalp vein needle introduced perpendicular to the skin surface, and contrast medium (nonionic iodine, 300 mg/ml) is injected into the lower joint space (Fig. 18-17A). Contrast medium is injected until optimum visualization of the joint space has been achieved, as determined by fluoroscopic observation of the joint space. Usually between 0.2 and 0.4 ml of contrast medium is injected. The needle is then withdrawn from the joint space, but the tip of the needle is left in the soft tissue lateral to the joint. The patient is asked to open and close the mouth several times while the image is recorded on videotape. The free flow of contrast medium around the top of the condyle and into the anterior recess of the inferior space indicates a successful injection. Simultaneous filling of the upper joint space indicates a perforation of the disk or retrodiskal attachments. In joints with perforation, additional contrast medium usually needs to be injected for optimum image quality. Spot films are obtained in at least the closed- and open-mouth positions and at additional positions where abnormalities are clearly seen.

If the diagnosis is not clear from these images, it may be helpful to also inject contrast medium into the upper joint space (Fig. 18-17B). This can be done either by withdrawing the needle slightly and then directing it superiorly into the upper joint space (if the needle was left in place after the initial injection) or by reinserting it while the patient is holding the mouth half open. Injection of the upper joint

space allows clearer delineation of the disk because both its inferior and superior surfaces are now coated by contrast medium.

Technique for Double-Contrast Arthrography

If double-contrast arthrography is to be performed, the joint spaces are punctured with catheters (Angiocath 0.8 mm in diameter and 25 mm in length) instead of needles.[17, 25] Contrast medium is injected via extension tubes and aspirated after the dynamic phase of the study. Room air is then injected via new extension tubes, and images are obtained on an upright tomographic unit such as the Phillips polytome. A complete description of the double-contrast technique is given elsewhere.[72]

Arthrographic Findings of the Normal TMJ

In a normal TMJ, the posterior band of the disk is located superior to the condyle in the so-called 12 o'clock position relative to the mandibular condyle (Fig. 18-18). The lower joint space has a relatively small anterior recess. However, studies of normal individuals without symptoms have shown great variation in the size of this recess despite the location of the disk in the superior position.[73] At maximum opening the disk is located inferior to the articular tubercle, and the

condyle articulates with the central thin zone and the posterior part of the disk (Fig. 18-18).

Abnormal Findings

Displacement of the disk with reduction (Fig. 18-19) and without reduction (Fig. 18-20) are the most frequent pathologic findings in TMJ arthrography. Principally this means that the posterior thick part (posterior band) of the disk is located anterior to the condyle in the closed-mouth position, and the condyle closes on the posterior disk attachment (bilaminar zone). An arthrographic sign of disk displacement in single-contrast lower compartment arthrography is enlargement of the anterior recess of the lower joint space (Fig. 18-19).

In disk displacement with reduction the disk is usually biconcave, although there may be some minor enlargement of the posterior band. This corresponds to the early-intermediate stage in the classification scheme described by Wilkes[9] (Box 18-2). In disk displacement without reduction a more extensive deformity of the disk is frequently encountered, and this corresponds to the late stage in the same classification scheme.[9] This is consistent with the deformities observed in pathologic specimens, which include thickening and shortening of the anteroposterior dimension of the disk. Perforation of the posterior disk attachment is another sign of late-stage internal derangement. Perforation is indicated by passage of contrast medium from the lower to the upper joint space (Fig. 18-21) when only the inferior space is injected.

Demonstration of pathology other than internal derangement is distinctly uncommon at TMJ arthrography. Patients with symptoms such as clicking and locking may occasionally have one or more loose bodies within the joint space.[74] Synovial chondromatosis, osteoarthrosis, or osteochondritis dissecans are the three principal causes of loose bodies in a joint.

Inflammatory joint disease such as rheumatoid arthritis is another pathologic entity that may affect the TMJ. However, this is usually diagnosed clinically, and patients with these diseases are rarely seen for TMJ arthrography. Osseous changes associated with rheumatoid arthritis can be clearly demonstrated with tomography or CT.

Complications Following Arthrography

Serious complications after arthrography are rare; no cases of infection following arthrography have been reported in the literature. Transient facial nerve palsy may result from extensive injection of a local anesthetic agent around the condyle and condylar neck, and the patient may have mild to moderate local discomfort for 1 to 2 days after the procedure. The use of nonionic or low-osmolality contrast media has been helpful in reducing the patient's discomfort.

Computed Tomography

CT scanning gives excellent definition of the bony contours of the mandibular head and the glenoid fossa. Axial imaging gives good definition of the head of the condyle, but sagittal and coronal planes are needed for evaluation of the actual joint surfaces. Though direct sagittal scanning of the TMJ (Figs. 18-22 and 18-23) has been done in the past, most institutions use axial scanning with sagittal reconstructions.[75–77] Both techniques have been reported to be successful in demonstrating internal derangement and

osseous disease.[78–80] Currently, multidetector CT scan technology using very thin collimation allows coronal and sagittal reformatted images that rival direct scan images (Fig. 18-24). The use of CT for diagnosis of disk position has decreased rapidly during the past decade because of the superiority of MR imaging with surface coils (Fig. 18-25).[81] Although CT is not used for visualization of the disk, it is still the best means of examining the osseous structures of the joint.

The two main reasons to use CT in evaluation of the TMJ today are for evaluation of fractures and postsurgical changes involving the osseous components of the joint. Thus, CT can clearly demonstrate the integrity of the glenoid fossa and note the presence of extensive erosions. Perforation into the middle cranial fossa after alloplastic implants also is shown best on CT.

CT is also frequently used for evaluation of potential pathology in the contiguous tissues. Although MR imaging has certain advantages in evaluation of soft tissues, CT gives excellent information regarding the soft tissues and has the benefit of providing detailed images of the contiguous temporal bone and skull base. Calcifications are more easily appreciated on CT. This information can be gathered with the same single scan acquisition done to provide the images of osseous components of the joint.

Technique for CT Scanning

Sagittal images are preferable to axial or coronal images for disk visualization. Coronal and sagittal images are equally good when evaluating the integrity of the roof of the glenoid fossa, a common indication for CT in patients who have received alloplastic TMJ implants. Axial scanning is

performed with 1 mm (or less) collimation, and sagittal and coronal images are reformatted from the original axial data. Three-dimensional reformatted images can be generated from the same data set (Fig. 18-26).

Before the advent of spiral CT machines, direct sagittal imaging required patients to be placed in uncomfortable positions, with the neck bent sharply to one side. In some cases, an additional stretcher was used to position the patient in the direct sagittal CT imaging plane.[75, 76] The stretcher was placed laterally at an angle with respect to the scanner table and the scanner gantry. Once the patient was in the correct position, scans were performed at 1 to 2 mm intervals from the medial to the lateral poles of the condyle. Additional images were obtained at maximum mouth opening. To minimize radiation, open-mouth images were taken in only a single plane through the center of the

FIGURE 18-24 Multidetector CT with sagittal reformats. Normal TMJ. **A**, Sagittal reformatted image; the bone algorithm shows the normal relationship of the condyle to the glenoid and the articular eminence. **B**, Soft-tissue sagittal reformat shows a small focus of high density (*arrow*) just anterior to the condylar head. This represents the anterior thick band. This position is considered to be normal.

condyle. CT scans are reconstructed for both bone detail and soft-tissue detail, eliminating the need for conventional radiography or tomography.

CT Findings

When the disk is normal and thus positioned superior to the condyle, it is usually relatively difficult to visualize (Fig. 18-24). Indeed, the inability to see the disk anterior to the condyle and inferior to the tubercle has been interpreted as a diagnosis of normal disk position (Fig. 18-25). The lateral pterygoid fat pad is the fat around the lateral pterygoid muscle. Some fat is also seen between the two bellies of the lateral pterygoid muscle. If the disk is dislocated, it will distort this fat (Fig. 18-27). Scans with a wide mouth opening usually produce optimum images of the disk but are seldom performed, as MR imaging has become the preferred modality for identifying the disk and its position.

When the disk is anteriorly displaced, it appears as a high-attenuation small mass anterior to the condyle, inferior to the tubercle, and within the low-attenuation lateral pterygoid fat pad (Fig. 18-27). The configuration of the disk typically cannot be determined by CT because the soft-tissue separation is not sufficient for this purpose. The depiction of the disk on CT depends on the disk's density and size. Thus, if the disk is thin and small, it usually is not identified on CT, leading to a higher incidence of false-negative diagnoses. On the other hand, if the disk is large, it can be demonstrated by CT.

Magnetic Resonance Imaging

MR imaging has been used to image the TMJ since 1984, and imaging quality has continuously improved since that time.[1, 10, 82–89] A major advantage of MR imaging over all other radiographic imaging techniques is the absence of radiation to the patient. This is especially pertinent for TMJ imaging, because a significant number of the patients are young females.[64] The soft-tissue differentiation of MR imaging is also superior to that of all other imaging modalities that have been applied to this joint, and at this time MR imaging is the primary imaging technique for most clinical presentations.

The objective of MR imaging of the TMJ is to document soft- and hard-tissue abnormalities of the joint and its surrounding structures. The ability of MR imaging to visualize the soft-tissue structures around the joint is another advantage of this modality over arthrography, and a comparison of these two imaging modalities on the same joint shows this fact (Fig. 18-28).

Magnetic Field Strength and Comparison with CT

Scanners with magnetic field strengths ranging from 0.05 to 2 Tesla are currently in clinical use; however, studies that compare the image quality of these scanners with different magnetic field strengths are scarce. One study compared images from two different scanners obtained with equal acquisition time and demonstrated significantly better image quality with the high-field system (Fig. 18-29).[90] Although the lower image quality of the 0.3 Tesla scanner could be somewhat compensated for by increasing the acquisition time (the number of excitations) by a factor of about 4, in clinical work this increases the risk of motion artifact.[90]

Some principal advantages and disadvantages of MR imaging compared with CT are outlined in Box 18-3. Contraindications for MR imaging are outlined in Box 18-4.

Surface Coil and Scanning Technique

The oblique sagittal and oblique coronal planes are standard for MR imaging of the TMJ (Fig. 18-30). A standard imaging protocol is shown in Table 18-1. The use of the dual surface coil technique for imaging of the left and

Copyright © 2003, Mosby, Inc. All rights reserved.

right TMJs at the same time has been of great value because the time on the scanner can be significantly shortened for bilateral TMJ imaging.[91, 92] Bilateral abnormalities are seen in up to 60% of patients with pain and dysfunction who initially present with unilateral symptoms.[93, 94]

MR imaging is performed using the body coil as the transmitter and the two surface coils as the receivers. Surface coils are essential for good image quality, and a diameter between 6 and 12 cm provides an optimal signal-to-noise ratio in most patients. The standard imaging protocol obtains oblique sagittal and oblique coronal images perpendicular and parallel to the long axis of the mandibular condylar head (Fig.18-30).[95] Sagittal images should be obtained in both closed- and open-mouth positions to determine the function of the disk. Coronal images are usually obtained only in the closed-mouth position. The protocol shown in Table 18-1 may need to be adjusted, depending on the performance of the scanner and the type of surface coils used.

Proton density images are preferable to T1-weighted images for outlining morphology because of the ''greater latitude'' and better visualization of disk tissue relative to the surrounding joint capsule and cortical bone. T2-weighted images are obtained routinely to document the presence of joint effusion and inflammatory changes in the joint capsule. Because of the arthrographic effect created by the high signal intensity of the joint effusion on T2-weighted images, these images also may be useful for outlining perforations. T2-weighted images obtained in both sagittal and coronal planes frequently help outline the joint effusion.

Fast spin-echo T2-weighted images provide a better signal-to-noise ratio than standard T2-weighted images.

However, the standard proton density images provide superior soft-tissue separation, and many imagers prefer standard spin-echo images because they are sharper than fast spin-echo images. Open-mouth images are obtained to determine the function of the disk. Syringes of various sizes or commercially available bite block devices are used to stabilize the patient's jaw in the open-mouth position (Fig. 18-31). Slice thickness should be 3 mm or less. The gap or interval between slices should be 0.5 to 1.5 mm for the sagittal images; for the coronal images it should be reduced to about 0.3 mm to obtain at least one good image through the center of the condyle. The anteroposterior dimension of the condyle is usually about 8 to 10 mm, and volume averaging is a greater problem for coronal images than for sagittal images. By angling the coronal images along the horizontal long axis of the condyle, images of both left and right joints can be obtained simultaneously. In the rare instance in which the slices of the left and right joints interfere with each other, separate scans of the left and right joints should be obtained.

The coronal images are valuable in identifying medial and lateral displacements of the disk. Additionally, the osseous anatomy of the condyle can sometimes be better appreciated in the coronal plane.

If the patient's oral splint is to be assessed, additional oblique sagittal images are obtained with the splint in place. The same scanning parameters are used for the closed-mouth sagittal images.

MR Imaging Findings of the Normal TMJ

MR imaging nicely shows the normal TMJ anatomy in the sagittal and coronal planes (Figs. 18-32 and 18-33). In the sagittal plane the disk is biconcave, with the posterior band (posterior thick part) lying over the condyle. The central thin zone articulates against the anterior prominence of the condyle. Because the fibrous connective tissue of the

FIGURE 18-27 Direct sagittal CT scan with a soft-tissue setting depicting an anteriorly displaced disk. The image of the disk has a relatively high CT attenuation contrasted against the fat close to the lateral pterygoid muscle. The arrow points to the thin portion of the disk.

disk has low signal intensity, the disk usually can be distinguished from the surrounding tissues, which have higher signal intensity. The cortices of both the condylar and temporal bone components of the joint have low signal intensity, but the articular coverings of the joint have higher signal intensity. This makes the outline of the osseous components easily visible. The posterior disk attachment has relatively high signal intensity compared with the posterior portion of the disk itself because of the fatty tissue in the posterior disk attachment. MR imaging is the only modality that consistently allows the disk to be distinguished from its posterior attachment.

The upper and lower heads (or bellies) of the lateral pterygoid muscle are seen extending anteriorly from the TMJ. The upper belly can be followed into the anterior margin of the disk. The lower belly attaches to the anterior surface of the condylar neck. There is a thin, fibrous band at the junction of the upper and lower heads at the point where the muscles reach their attachments to the disk and condyle. This fibrous band is seen as a linear low-signal structure just inferior to the position of the disk, and it should not be mistaken for the disk. This is a particular problem when the disk is medially or laterally displaced and the fibrous band of the lateral pterygoid muscle is the only low-signal structure anterior to the condylar head.

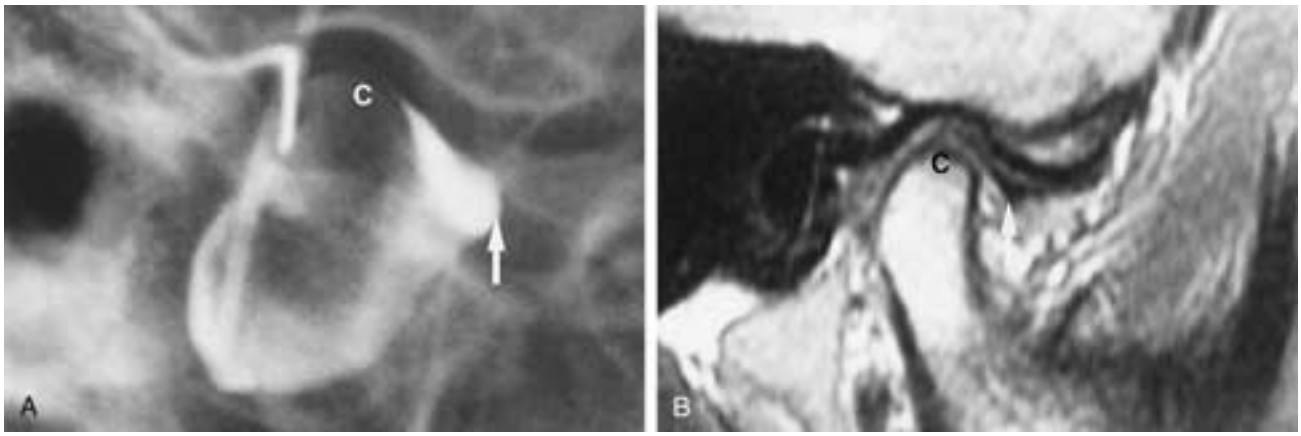
In MR imaging scans obtained at maximum mouth opening, the central thin zone of the disk is visualized between the condyle and the tubercle (Fig. 18-33B). The posterior band of the disk articulates against the posterior surface of the condyle, as has been demonstrated in anatomic specimens (Fig. 18-3).

In the coronal plane (Fig. 18-33C), the normal disk has a crescent shape. The medial aspect of the disk attaches just inferior to the medial pole of the condyle and to the medial capsule. Similarly, the lateral part of the disk attaches just inferior to the lateral pole of the condyle and to the lateral capsule (Fig. 18-2). Normally, the lateral and medial capsules are visualized and do not bulge outward.

Disk Displacement

Displacements of the disk in the anterior (Fig. 18-34), anteromedial, or anterolateral direction are the most common findings observed when interpreting MR images of patients with clinical signs and symptoms of internal derangement.[43] In the sagittal plane the disk is noted to be displaced when its posterior band is anterior to the condyle (Fig. 18-34).

Disk displacement may be complete or partial. In complete disk displacement, the entire mediolateral dimension of the disk is displaced anterior to the condyle. In partial disk displacement, only the medial or lateral part of the disk is displaced anterior to the condyle. Most frequently, the lateral part is displaced anteriorly and the more medial part of the disk is still in a normal superior position. Partial disk displacement is frequently seen in joints with disk displacement with reduction (Fig. 18-35); the disk is displaced anteriorly in the lateral part of the joint (Fig. 18-35A) and is in a normal position in the medial part of the joint (Fig. 18-35B). This is probably because the displaced part of the disk, being anchored by the normally positioned medial



VIEW IMAGE

portion of the disk, is allowed to revert to its normal position on opening without being squeezed between the two joint components as much as in cases with a complete anterior disk displacement.

Frequently, the anterior disk displacement is combined with either medial or lateral displacement. Initially, when MR imaging was done in the true coronal plane, medial displacements were considered more prevalent than lateral displacements. This was probably the result of the scanning technique rather than pathologic changes because, with oblique coronal images parallel to the horizontal long axis of the condylar head, medial and lateral displacements are seen with approximately the same frequency. In most cases, the sagittal images show the anterior component of the displacement, and the coronal images show the medial or lateral component. In approximately 10% of patients

BOX 18-3

ADVANTAGES AND DISADVANTAGES OF MR IMAGING COMPARED WITH CT

Advantages	No ionizing radiation
	Fewer artifacts from dense bone and metal clips
	Imaging possible in several planes without moving the patient
	Superior anatomic detail of soft tissues
Disadvantages	High initial cost of the scanner Special site planning and shielding
	Patient claustrophobia in magnet
	Inferior images of bone

BOX 18-4

CONTRAINDICATIONS TO MR IMAGING

Absolute	Patients with cerebral aneurysm clips
	Patients with cardiac pacemakers
Relative	Ferromagnetic foreign bodies in critical locations (e.g., eyes)
	Metallic prosthetic heart valves
	Claustrophobic or uncooperative patients
	Implanted stimulator wires for pain control
Not contraindications	Metallic prostheses
	Orthodontic fixed appliances

It is important to cover the area of the lateral and medial poles of the condyle with the sagittal images. For the coronal images, one image should be through the center of the condyle.

presenting with TMJ pain and dysfunction, there is a pure lateral or pure medial disk displacement that is not detected on sagittal images (Fig. 18-36).[10] The displacement can be dramatic in both the lateral (Fig. 18-36) and medial (Fig. 18-37) directions. When the disk is displaced medially or laterally in combination with anterior displacement, it is called rotational disk displacement (Box 18-1).

The empty fossa sign seen in the sagittal images (Fig. 18-38) is an indication of a medial or lateral disk displacement. When the disk displaces in a medial direction, the lateral capsular tissue is pulled between the condyle and glenoid fossa and gives the appearance of an ''empty'' fossa. Thus, when the disk is not clearly seen in the glenoid fossa in the closed-mouth position (Fig. 18-38), medial or lateral disk displacement should be suspected. The coronal images are examined for verification. Medial and lateral disk displacement may or may not (Fig. 18-38) reduce on

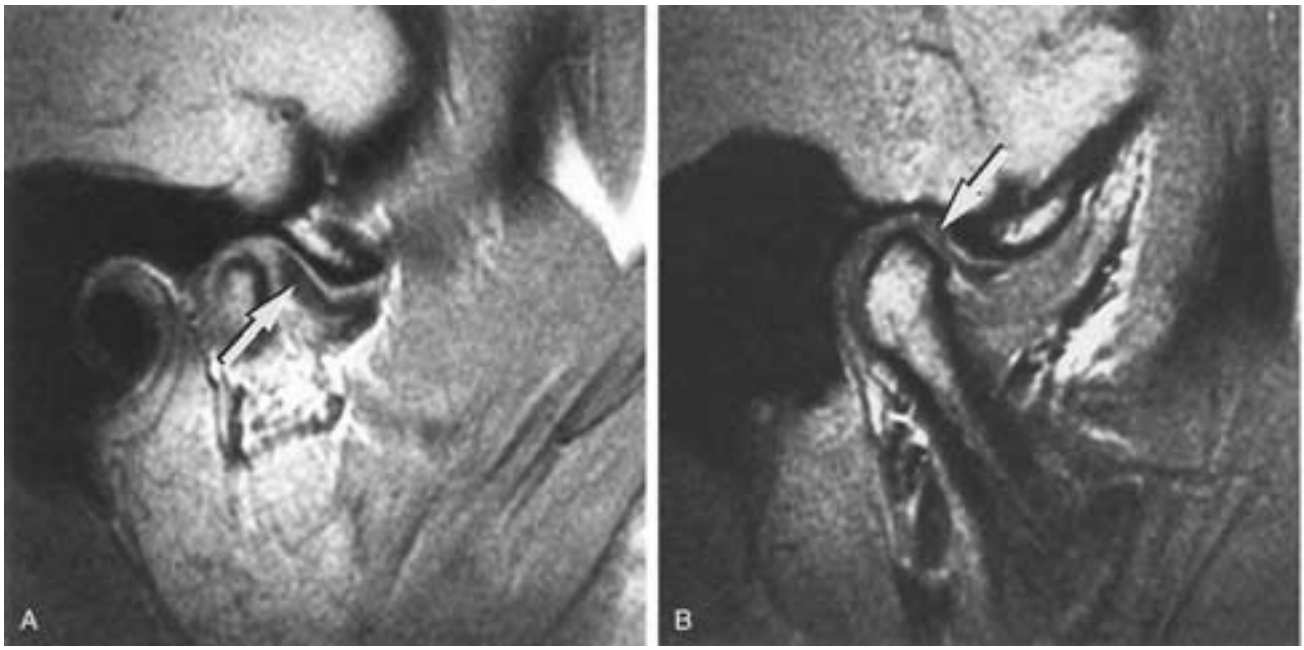
opening. The function of the disk with sideways displacement is more difficult to evaluate than with anterior displacement because the location of the disk is best seen in the coronal plane in the closed position and the sagittal plane in the open position.

MR images obtained at maximum mouth opening determine whether the disk displacement reduces. In displacement with reduction (Fig. 18-34) the disk position normalizes during jaw opening. In disk displacement without reduction (Fig. 18-39) the disk remains anterior to the condyle in all mandibular positions. Disk displacement with reduction practically always precedes late-stage disk displacement without reduction.

Disk Deformity

Deformity of the disk (Fig. 18-9) resulting from chronic displacement can usually be demonstrated by MR imaging (Fig. 18-40). Initial deformity includes thickening of the



VIEW IMAGE

posterior band. Late-stage deformity may include a rounder, biconvex disk or a severely diminished amount of disk tissue. Disk deformation is significant in the clinical management of patients because a deformed disk usually cannot be repositioned surgically, and more aggressive surgical treatment with diskectomy may be necessary. It is therefore important to evaluate the degree of disk deformity and communicate this information to the referring clinician.

Another form of tissue alteration secondary to disk displacement is the formation of the so-called pseudodisk (Fig. 18-41). A pseudodisk appears as a band-like structure of low signal intensity replacing the normally bright signal from the posterior disk attachment. Histologically, it is thought to represent the fibrotic change that occurs in the posterior disk attachment in response to pressure from the condyle against the loose tissue of the posterior disk attachment (bilaminar zone). It has been suggested that this fibrotic change in the posterior disk attachment is associated with decreasing pain, but this has not been confirmed in systematic studies.[96, 97]

Other Findings and Conditions Related to Internal Derangement

Joint Effusion

An assessment of the amount of joint fluid is essential because small amounts of fluid are seen outlining the articular surfaces in both normal and abnormal individuals (Fig. 18-42).[98] Large accumulations of joint fluid (Fig. 18-43) are seen only in symptomatic patients. Such effusions are best seen in T2-weighted MR imaging.

Joint fluid is significantly more prevalent in painful joints than in nonpainful joints.[98] Not all individuals with pain have joint effusion, but a significant accumulation of joint effusion is likely to be associated with pain and the status of the disk.[99–101] Joint effusion may also have some diagnostic value, as the fluid outlines the morphology of the disk and may outline a perforation in the posterior disk attachment (Fig. 18-44).

Osteoarthritis

Osteoarthritis is frequently seen in joints with long-standing disk displacement without reduction.[18, 26] Disk displacement seems to be a precursor of osteoarthritis. Osteoarthritis is infrequently seen in joints with a normal superior disk position, occasionally in disk displacement with reduction, and more frequently when disk displacement without reduction has been present for some time. Imaging evidence of osteoarthritis can be seen in teenagers with disk displacement without reduction. Disk displacement and internal derangement are, however, only one cause of osteoarthritis, the common final pathway for a multitude of primary joint lesions.

Osteoarthritis is characterized radiographically by flattening and irregularities of the articular surfaces, osteophytosis, and erosion (Figs. 18-45 and 18-46). There may be irregularity of the glenoid fossa, particularly when there is bone-to-bone contact because of a tear in the disk or retrodiskal tissues. The distinction between early arthritis and advanced remodeling on MR imaging, as well as on other imaging modalities, is difficult to define, and overlap will exist.

Osteoarthritis has been suggested as a source of pain. However, osteoarthritis is present in a large proportion of older individuals and is usually completely asymptomatic. It is well recognized that symptoms related to TMJ dysfunction decrease with age, and are often remitting and self-limited.[102–105] The discrepancy between imaging findings and patient symptoms indicates the need for a good clinical examination to determine which imaging findings are significant.

FIGURE 18-37 Medial disk displacement. Coronal MR image shows the disk (*arrows*) displaced medial to the condyle.

VIEW IMAGE

Marrow Abnormalities of the Mandibular Condyle

Claims have been made, based on comparison with other joints, that areas within the bone marrow of the condyle having low signal intensity on T1-weighted images (variable signal on T2-weighted images) represent osteonecrosis (avascular or aseptic necrosis) (Figs. 18-47 to 18-50).[89, 106] However, based on this MR imaging appearance, other etiologies such as sclerosis or fibrosis of the bone marrow cannot be ruled out.

Multiple MR imaging studies have described abnormalities of the mandibular condyle similar to the appearance of osteonecrosis (aseptic necrosis) in the femoral head.[107–111] One study used core biopsy to document that edema and osteonecrosis may occur in the marrow of the mandibular condyle.[112] Histologic evidence of bone marrow edema was also found without evidence of osteonecrosis, suggesting that edema may be a precursor to osteonecrosis, as is known from investigation of other joints.[112] MR findings suggesting bone marrow edema include intermediate signal intensity on T1-weighted and proton density images and increased signal intensity on T2-weighted image (Fig. 18-48).

Osteoarthritis may develop secondary to osteonecrosis in the TMJ (Fig. 18-50).[112, 113] However, edema and osteonecrosis are separate entities from osteoarthritis and do occur without osteoarthritis.[113]

Avascular necrosis is best characterized in the hip. Predisposing factors include sickle cell disease, alcoholism, and steroid therapy. Avascular necrosis in the mandibular condyle probably has a different etiology and has not been associated with the same systemic factors but rather with local trauma from internal derangement.[89] Disk displacement may be one factor that leads to bone marrow changes.[109–111, 113, 114]

Abnormal bone marrow of the mandibular condyle may be seen in less than 10% of joints with TMJ disease.[113, 115] A study has shown markedly greater pain in joints that have bone marrow alterations in the mandibular condyle compared to joints with normal bone marrow.[116] Increased intraarticular pressure in conditions such as synovitis and hemophilia has also been suggested as an etiology of osteonecrosis.[117] A relationship between osteonecrosis and larger amounts of joint fluid has also been described.[111, 112]

This is termed an *empty fossa*. **B**, On opening, the disk (*arrow*) is seen. **C**, The coronal image (closed mouth) shows the disk (*arrows*) medially displaced. The empty fossa is an indication of medial or lateral disk displacement.

VIEW IMAGE

Osteochondritis Dissecans

Loose bodies are seldom found in the TMJ. One loose body in the joint space associated with a defect in the condyle of the same size can be characterized as osteochondritis dissecans.[89] In this condition, a small part of the condyle is dislodged into the joint space and acts as a small, loose body (Fig. 18-51). The condition has been described as being associated with avascular necrosis, although the relationship between the two conditions is not fully understood.[89] Osteochondritis dissecans has been demonstrated in a cadaver joint (Fig. 18-52). Multiple loose bodies are discussed in the section on Synovial Chondromatosis.

Stuck Disk

In the normal opening sequence, the disk moves relative to both the condyle and the temporal bone component of the joint. Most of the movement in the upper joint compartment represents translation. The disk slides or translates relative to the glenoid. In the lower joint compartment the predominant motion is rotation. The condyle rotates within the concavity of the disk. Translation or sliding of the condyle relative to the disk is normally minimal. It has been suggested in the arthroscopic literature that inability of the disk to move, relative to the glenoid fossa, is a significant cause of pain and dysfunction.[28] This observation has not been extensively and systematically documented, but there

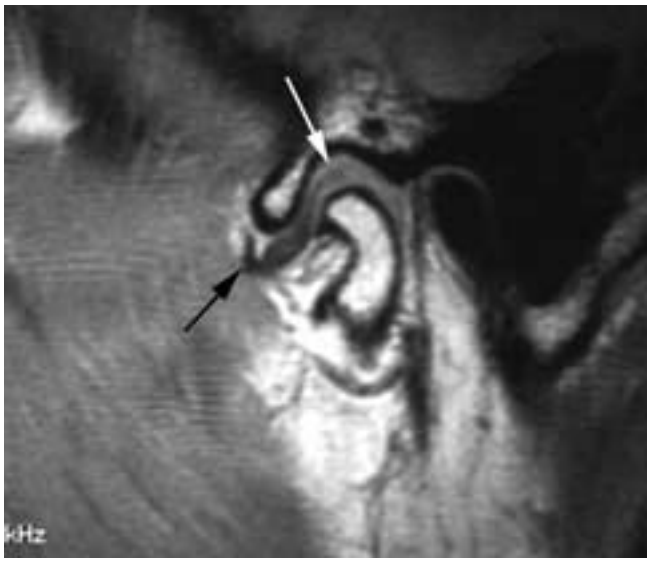
FIGURE 18-39 Anterior displacement without reduction (closed lock). **A**, The head of the condyle is posteriorly positioned in the glenoid fossa. The posterior thick band of the disk (*arrow*) is completely anterior to the condylar head. **B**, Upon opening of the mouth, the condyle moves to a point just inferior to the articular eminence. Rather than recapturing the disk, it pushes the disk anteriorly and does not regain the normal relationship.

are indications that MR definition of a stuck disk (Figs. 18-53 and 18-54) may be associated with pain and dysfunction.[118] As the patient opens the mouth, the disk maintains a constant relationship to the glenoid while the condyle rotates and may translate relative to the disk.

Lock

The most frequent situation with locking of the TMJ is the inability of the patient to open the mouth completely. This is most frequently caused by anterior disk displacement without reduction.



VIEW IMAGE

FIGURE 18-40 Disk deformation. The disk is anteriorly displaced. There is thickening of the posterior band (*black arrow*) and folding of the disk. The lack of signal from the retrodiskal attachments (*white arrow*) suggests fibrosis secondary to the chronic trauma of the dislocation.

The open lock condition is encountered more infrequently. In this condition, the patient can open the mouth widely but is temporarily or permanently unable to close the mouth. This condition sometimes requires manipulation of the jaw by the patient or a health care professional to move the mandible into place. These patients frequently present in the emergency room but rarely for imaging assessment.

There are two different causes of the open lock condition.

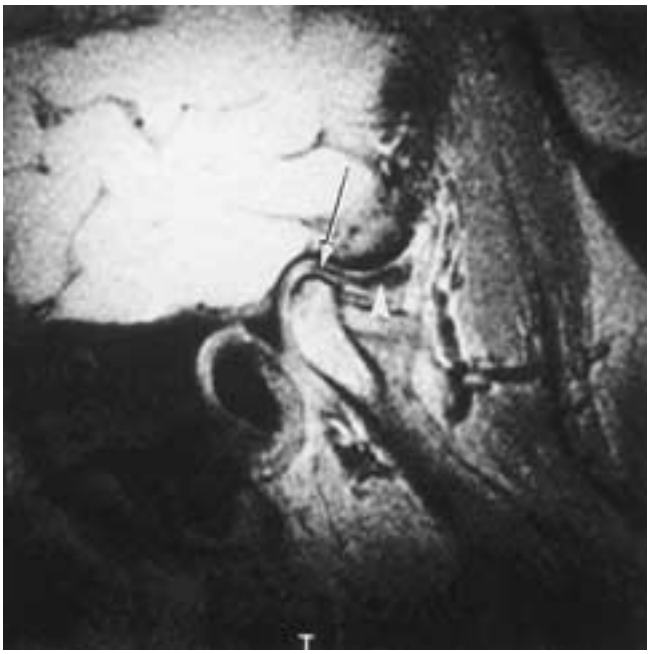


FIGURE 18-41 Fibrosis of the posterior disk attachment. The disk (*arrowhead*) is anteriorly displaced. There is an area of low signal in the posterior disk attachment (*long arrows*), which indicates fibrosis.

VIEW IMAGE

In the classic situation, the condyle is luxated (subluxed or dislocated) in front of the articular eminence, and the articular eminence prevents the condyle from retruding back into the glenoid fossa. In the other situation, the condyle translates anteriorly to the anterior band of the disk, and the disk prevents the condyle from retruding back into the glenoid fossa (Fig. 18-55). Characteristically, in this situation the disk is folded behind the condyle (Fig. 18-55). It is usually not possible to differentiate between the two causes on physical examination. Although acute management with reduction of the subluxation is similar in both situations, if definitive surgery is necessary, it differs depending on the cause of the subluxation. If the disk is blocking the reversion of the condyle, surgery has to be directed to the disk. If the articular eminence is the cause of the patient's inability to close the mouth, surgery must focus on the bone.

Accuracy of TMJ Imaging

Knowing the diagnostic accuracy of an imaging modality is essential for its clinical use. The accuracy of tomography, arthrography, CT, and MR imaging has been investigated in several studies on fresh autopsy material (Tables 18-2 and 18-3 on p. 1029).[81, 119–122] All techniques have demonstrated relatively high accuracy in determining osseous conditions and disk position; however, MR imaging has the highest accuracy and demonstrates both joint structures and the soft tissues surrounding the joint.

The accuracies noted in Tables 18-2 and 18-3 are from investigations performed without the biases of clinical work. The figures are relevant for the comparison between the different techniques because the studies were performed under the same conditions. In a clinical situation, however, additional information about the patient is available that

might help further improve interpretation of the image. In addition, by detecting medially or laterally displaced disks, the multiplanar imaging capability of MR imaging may provide even greater accuracy (Fig. 18-56). A recent study demonstrated the accuracy of MR imaging in determining disk position and configuration to be more than 90%.[123]

Imaging After Treatment

Imaging after surgical treatment is indicated in patients who continue to have symptoms that might be related to intraarticular pathology such as recurrence of disk displacement, intraarticular adhesions, or inflammatory changes. Although surgery is performed for a variety of pathologies of the jaw and TMJ, most surgery is done for patients with internal derangements. For this reason, imaging of the postoperative joint is discussed in this section.

The primary goal of treatment of TMJ disorders is to eliminate pain and dysfunction. Secondary goals are restoration of normal anatomy and prevention of disease progression. If a patient continues to have symptoms after treatment, imaging is frequently helpful in determining the etiology of the problem.

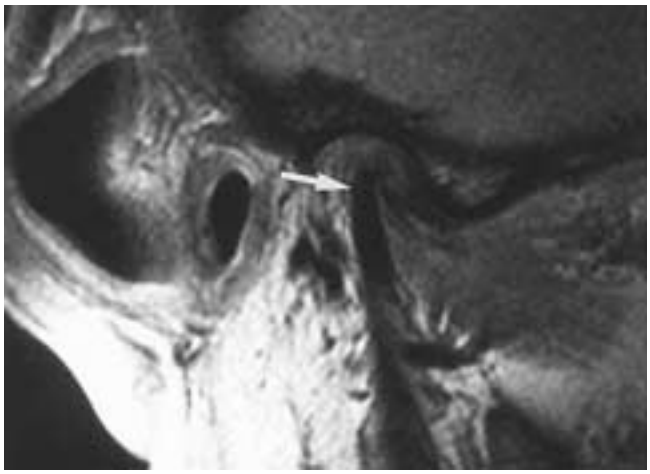
FIGURE 18-46 Osteoarthritis with erosion of the condylar head. **A**, Proton density MR image shows a defect (*arrowhead*) in the head of the condyle. The disk is completely dislocated anteriorly, with the posterior thick band (*arrow*) completely anterior to the condylar head. **B**, Open-mouth position. The condyle pushes the disk anteriorly but does not recapture. Note how the posterior thick band fits into the cortical defect (*arrowhead*) and the head of the condyle.

Treatment Modalities for TMJ Internal Derangement

Conservative treatment of TMJ internal derangement includes reassurance, observation, occlusal adjustment, bite splints, nonsteroidal antiinflammatory medications, muscle relaxants, and physical therapy. Arthroscopic surgery includes lysis and lavage of adhesions and disk repositioning. Open joint surgery includes disk repositioning, diskectomy without replacement, diskectomy with autologous implant, and joint reconstruction with rib grafts. The use of alloplastic disk replacement implants has been discontinued.



VIEW IMAGE

FIGURE 18-47 Sclerosis of the condyle and condyle neck. A proton density image shows decreased signal from the entire condyle head and condyle neck (*arrow*). This may indicate sclerosis, fibrosis, or possibly avascular necrosis. No histologic proof was available in this case.

Imaging Techniques after Surgical Treatment

Before the availability of MR imaging, plain films (Fig. 18-57), tomography, and arthrography were used to evaluate patients after surgery. Plain films and tomography show only the osseous structures, and there is often a need for soft-tissue evaluation as well. Arthrography can be difficult to perform once surgery has been done because the anatomy is altered and the joint spaces are narrowed as a result of peripheral and intraarticular adhesions (Fig. 18-58). For this reason, MR imaging is a preferable method of examination in most postoperative patients.[1, 82, 83]

Postoperative MR imaging is helpful in confirming whether surgical treatment has corrected the position of the displaced disk. Frequently, however, the disk remains anteriorly displaced after disk-repositioning surgery. This is seen in both symptomatic and asymptomatic individuals, and less emphasis should be placed on the position of the disk after surgery because symptoms may be associated more with peripheral adhesions than with disk position per se.

In patients who have undergone diskectomy, there is a soft-tissue interface between the condyle and the glenoid fossa (Fig. 18-59), which is a natural replacement for the extirpated disk.[124] This is a normal postsurgical development. On MR imaging this soft tissue has intermediate to high signal intensity compared to fibrous adhesions, which have low signal intensity (Fig. 18-60). The most important imaging assessment in these patients is to evaluate for peripheral or intraarticular adhesions following diskectomy, because such adhesions (Fig. 18-60) frequently are the cause of the patient's limited opening and pain. Thickening of the lateral joint capsule is also frequently seen after surgery (Fig. 18-61) in both symptomatic and asymptomatic individuals and is probably of limited clinical significance as long as the scar tissue does not extend into the joint space. The amount of scar tissue in the lateral capsule wall varies

significantly among patients; some scar tissue in asymptomatic patients is quite large but does not extend into the joint space (Fig. 18-61).

Complete fibrous (Fig. 18-60) or bony ankylosis may occur after surgery in a few instances. Jaw motion is severely restricted, but opening can be up to about 10 mm, even with a heavy fibrous ankylosis. In bony ankylosis there is no motion. CT or tomography is preferred over MR imaging for demonstration of these bony changes.

Alloplastic Implants

During the 1980s and early 1990s, alloplastic implants were used to replace the disk. Two types of implants, Proplast Teflon (Figs. 18-62 and 18-63) and silicone rubber material (Silastic) were mainly used. The Proplast implants were intended to be permanent, whereas the silicon implants were used either on a temporary or a permanent basis. The initial results were favorable and these surgical techniques

quickly gained popularity, although clinical studies to support long-term success were lacking. After about 2 to 4 years, patients frequently developed gradually increasing pain. This was later shown to be due to fragmentation of the implant material and a foreign body giant cell reaction to this material. Although the reaction to the particulated material was similar with both Silastic and Proplast, it seemed more aggressive with Proplast. Clinically, the patient presented with pain, and radiographically erosive changes of the bone have been observed (Fig. 18-64). The long-term prognosis for TMJ alloplastic implants is poor, and probably all implants eventually have to be removed.

While the implants are still in place, imaging evaluation is frequently necessary. The principal findings relate to the extent of erosive change of the glenoid fossa and the mandibular condyle. The integrity of the glenoid fossa is critical since erosions can extend into the middle cranial fossa (Fig. 18-63). For the initial evaluation of a patient with a TMJ alloplastic implant, both MR imaging (Fig. 18-62) and CT (Figs. 18-63 and 18-65) may be necessary. MR imaging shows the extent of the soft-tissue alteration (Fig. 18-62), fragmentation of the implant material, and expansion of the joint capsule. CT is valuable for assessment of bones, especially the integrity of the glenoid fossa (Fig. 18-63B). For follow-up examination, CT with coronal or sagittal images is the optimal imaging modality. Irregularity of the implant is best appreciated on CT. Sagittal or coronal CT images best demonstrate the implant and show erosive changes of the condyle most clearly. The status of the condyle following the temporary use of Silastic is best appreciated on CT, as is the bony ankylosis that may occur between the condyle and the glenoid fossa (Fig. 18-64).

FIGURE 18-51 Osteochondritis dissecans. Sagittal MR image shows a defect in the upper part of the condyle (*arrowheads*) and a corresponding structure in the glenoid fossa, which was interpreted as a loose body (*long arrow*). This condition is consistent with osteochondritis dissecans.

VIEW IMAGE

FIGURE 18-54 Stuck disk. **A**, In the closed-mouth position, the condyle has a normal relationship to the disk. The posterior edge of the posterior thick band (*arrow*) is located immediately superior to the condylar head. **B**, In the open-mouth position, the condyle has translated anteriorly and now is seated on the thick anterior portion of the disk. The disk has not moved relative to the glenoid and the articular eminence. Note that the posterior edge of the disk (*arrow*) remains at the same point as in the closed-mouth image.

Total Joint Replacement

Total replacement of the TMJ has been attempted for many years.[125, 126] There continue to be problems with stabilization of both the glenoid and condyle parts of the prosthesis, and these patients frequently present for imaging evaluation. In a situation where there are large metallic implants, neither CT nor MR imaging is feasible because of degradation artifacts. Plain films and tomography are the only imaging modalities available (Fig. 18-66). The assessment should concentrate on motion between the implant and the underlying bone, osteolytic changes of the bone, and evidence of loosening of the implant.

Costochondral Grafts

Costochondral grafts were formerly used for reconstruction of the TMJ and have recently regained popularity since the alloplastic joint prostheses have essentially been abandoned.[127] Imaging of costochondral grafts can be done with plain films, tomography, CT, and MR imaging. MR imaging gives good images of the cartilaginous part of the graft. CT shows the osseous part of the graft but does not show the cartilaginous segment as well (Figs. 18-67 and 18-68). The size and orientation of the cartilaginous segment are represented by the apparent gap between the osseous part of the graft and the skull base, and the cartilage itself can

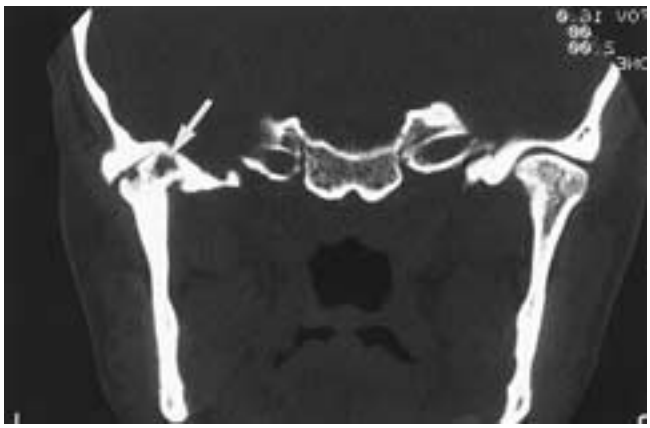
Also note that the implant is difficult to outline due to partial fragmentation.

sometimes be demonstrated. Points of contact between the osseous part of the graft and the skull base can be demonstrated, and sclerosis of the bone may be present. Fusion can occur, causing progressive limitation of opening. CT imaging with 3D reconstructions allows for a more graphic demonstration of the relationship between the joint components; however, portions of the cartilaginous graft are still not visualized (Fig. 18-69).

Metallic Artifacts

Metallic artifacts are frequently seen in MR imaging of postoperative osseous structures. The metallic artifact appears as an area of signal void bordered by areas of high signal intensity (Fig. 18-70). Even very small metallic particles can cause significant areas of loss of signal, and thus minuscule pieces shredded from metallic instruments used to scrape the bone could be sufficient to create a significant artifact. These small artifacts are seen in both symptomatic and asymptomatic patients after surgery, and they are probably of no clinical significance.[124] The most important aspect of the metallic artifact is that it may prevent further MR imaging.



VIEW IMAGE

FIGURE 18-64 Erosions and bony ankylosis following temporary Silastic implant. Coronal CT scans through the TMJ show extensive erosive changes of the right condyle. There is bony ankylosis between the condyle and the glenoid fossa and the medial part of the joint. The patient used a temporary Silastic implant for a few months. These extensive radiographic changes are the sequelae from the use of the implant.

MISCELLANEOUS CONDITIONS INVOLVING THE TMJ

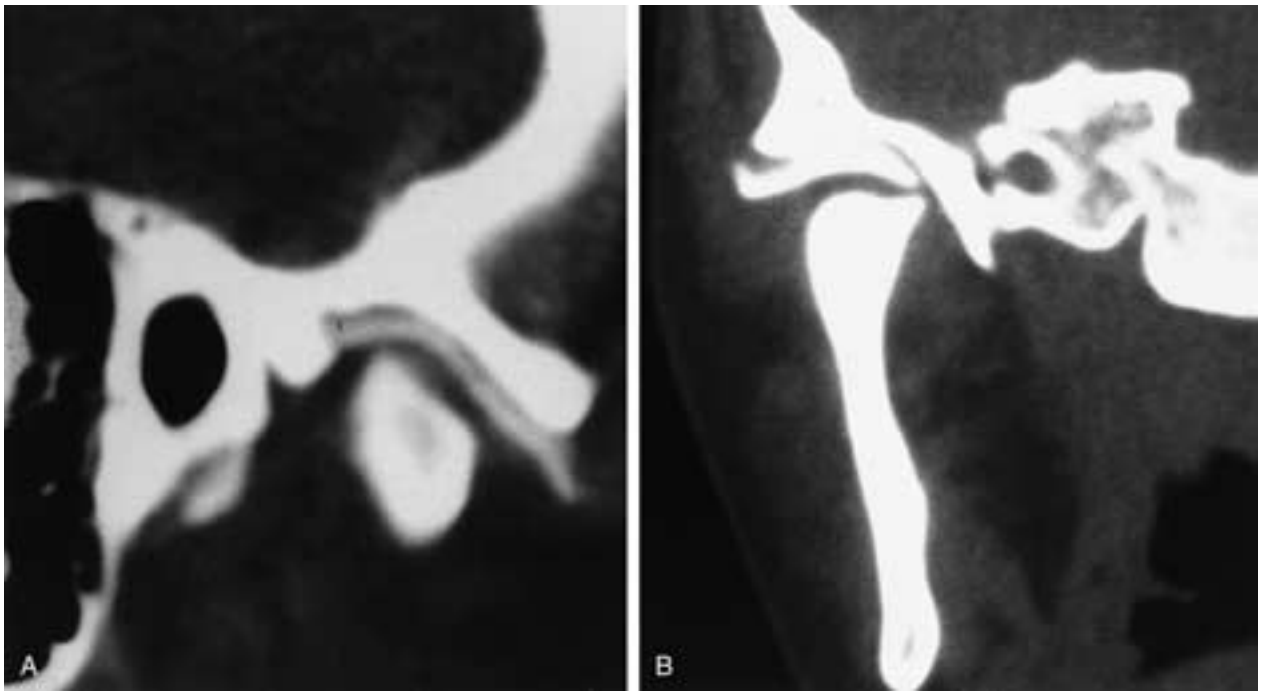
Though most imaging evaluations are done for possible internal derangements and their sequelae, many other types of pathology occasionally affect the TMJ. Tumors, systemic arthritides, and congenital anomalies may be found during an evaluation of the TMJ or during assessment for suspected pathology in the adjacent head and neck region.

Tumors and Tumor-Like Conditions of the TMJ

Synovial Chondromatosis

The TMJ is infrequently affected by tumors. The most common neoplastic lesion affecting the TMJ is probably synovial chondromatosis.[128, 129] This tumor can be locally aggressive, and cases with intracranial extension have been described.[130, 131] It is a benign lesion characterized by formation of multiple small ''pearls'' of cartilage, usually within the joint space. MR imaging can show synovial chondromatosis primarily affecting the upper joint space

Copyright © 2003, Mosby, Inc. All rights reserved.



VIEW IMAGE

FIGURE 18-65 CT scan in the sagittal (**A**) and coronal (**B**) planes showing an implant in a good position.

(Fig. 18-71) or both the upper and lower joint spaces (Fig. 18-72). There is often significant joint expansion, and there may be multiple areas of low signal intensity that represent the pearls (Fig. 18-72). The clinical presentation of patients with synovial chondromatosis is similar to the general presentation of TMJ pain and dysfunction, and the findings are usually detected with imaging studies or at surgery. Evaluation can be done with both MR imaging and CT.[132–134]

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis is a benign proliferative disease or tumor affecting the synovial lining of joints as well as tendons. There is nodular synovial proliferation and hemarthrosis. Pathology shows a mixture of histiocytes, giant cells, and spindle cells. There is evidence of hemorrhage with intracellular hemosiderin. The condition rarely involves the TMJ.[135–141] An enlarging mass is centered in the TMJ or the lesion may seem to extend away from the joint. The lesion tends to be dense on CT.

VIEW IMAGE

FIGURE 18-68 Costochondral graft CT. **A**, Coronal CT scan shows the osseous portion of the costochondral graft (*arrowheads*) attached to the lateral aspect of the native mandible (*M*). The chondral part of the graft (*arrow*) is seen as a lucency separating the osseous part of the graft from the glenoid. **B**, The cartilage portion of the graft (*arrow*) is seen more clearly on the sagittal reformatted image. Note that the edge of the osseous portion of the graft (*arrowhead*) is very close to the articular eminence.

The head of the condyle is usually eroded, and in more extensive cases the skull base may also be involved. The hemorrhage by-products give the lesion low signal on both T1- and T2- weighted images (Fig. 18-73). Indeed, the extensive iron deposition can give a pronounced susceptibility artifact, particularly on T2-weighted MR images.

Osteochondroma

Osteochondroma is probably the second most common neoplastic lesion affecting the TMJ. Osteochondroma (Fig. 18-74), osteoma, and condyle hyperplasia are difficult to differentiate clinically and on imaging studies. MR imaging can define these conditions in both the sagittal and coronal planes, but CT may delineate more precisely the extension of the tumor and its relationship to anatomic structures medial to the TMJ region.

VIEW IMAGE

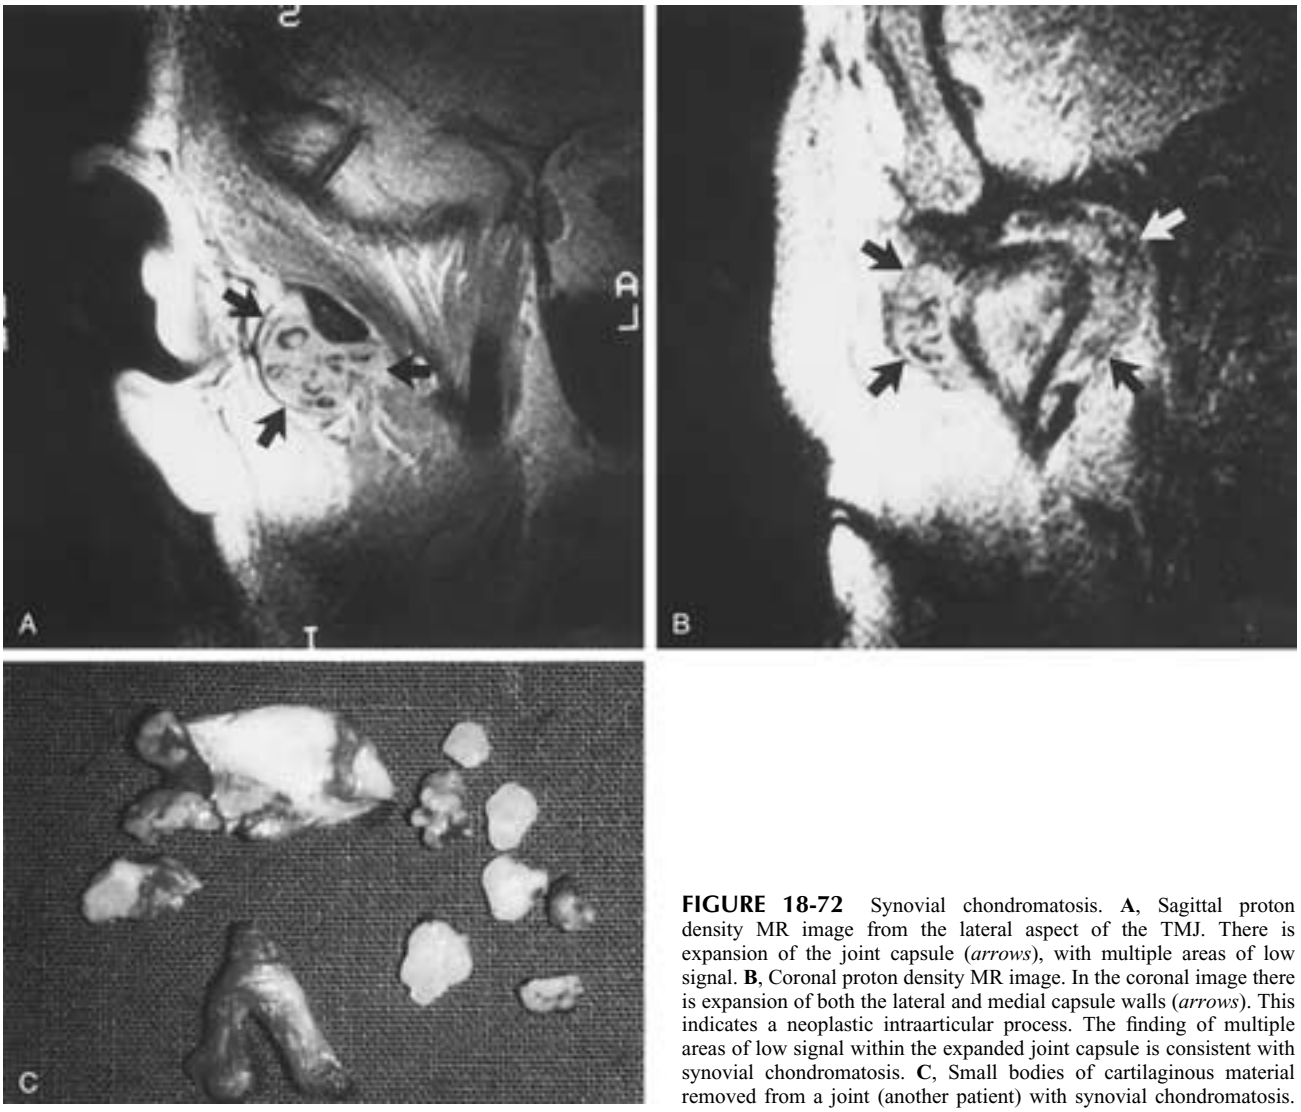
Calcium Pyrophosphate Arthropathy (Pseudogout)

Calcium pyrophosphate dihydrate (CPPD) deposition disease, or pseudogout, infrequently affects the TMJ. Involvement can be mild or quite severe. Mild cases of this condition have been described with subtle calcifications in the disk and in the joint space (Fig. 18-75).[142–144] Clinically, the patient presents with pain and dysfunction similar to the symptoms of other TMJ patients. There can be associated swelling and degenerative changes in the joint. CT is the best imaging modality for demonstration of the minute intraarticular calcifications. More extensive cases present with enlarging masses.[143, 145–147] Calcification can be demonstrated on a CT scan. There can be significant erosion of the contiguous skull base as well as the condyle. Malignancy may be suspected because of the apparent aggressiveness and bone ''destruction'' shown at imaging (Fig. 18-76). The pathology can also suggest sarcoma, and thus the importance of considering this benign diagnosis so that aggressive therapy inappropriate for this benign disease can be avoided.[145, 146, 148, 149]



VIEW IMAGE

FIGURE 18-72 Synovial chondromatosis. **A**, Sagittal proton density MR image from the lateral aspect of the TMJ. There is expansion of the joint capsule (*arrows*), with multiple areas of low signal. **B**, Coronal proton density MR image. In the coronal image there is expansion of both the lateral and medial capsule walls (*arrows*). This indicates a neoplastic intraarticular process. The finding of multiple areas of low signal within the expanded joint capsule is consistent with synovial chondromatosis. **C**, Small bodies of cartilaginous material removed from a joint (another patient) with synovial chondromatosis.

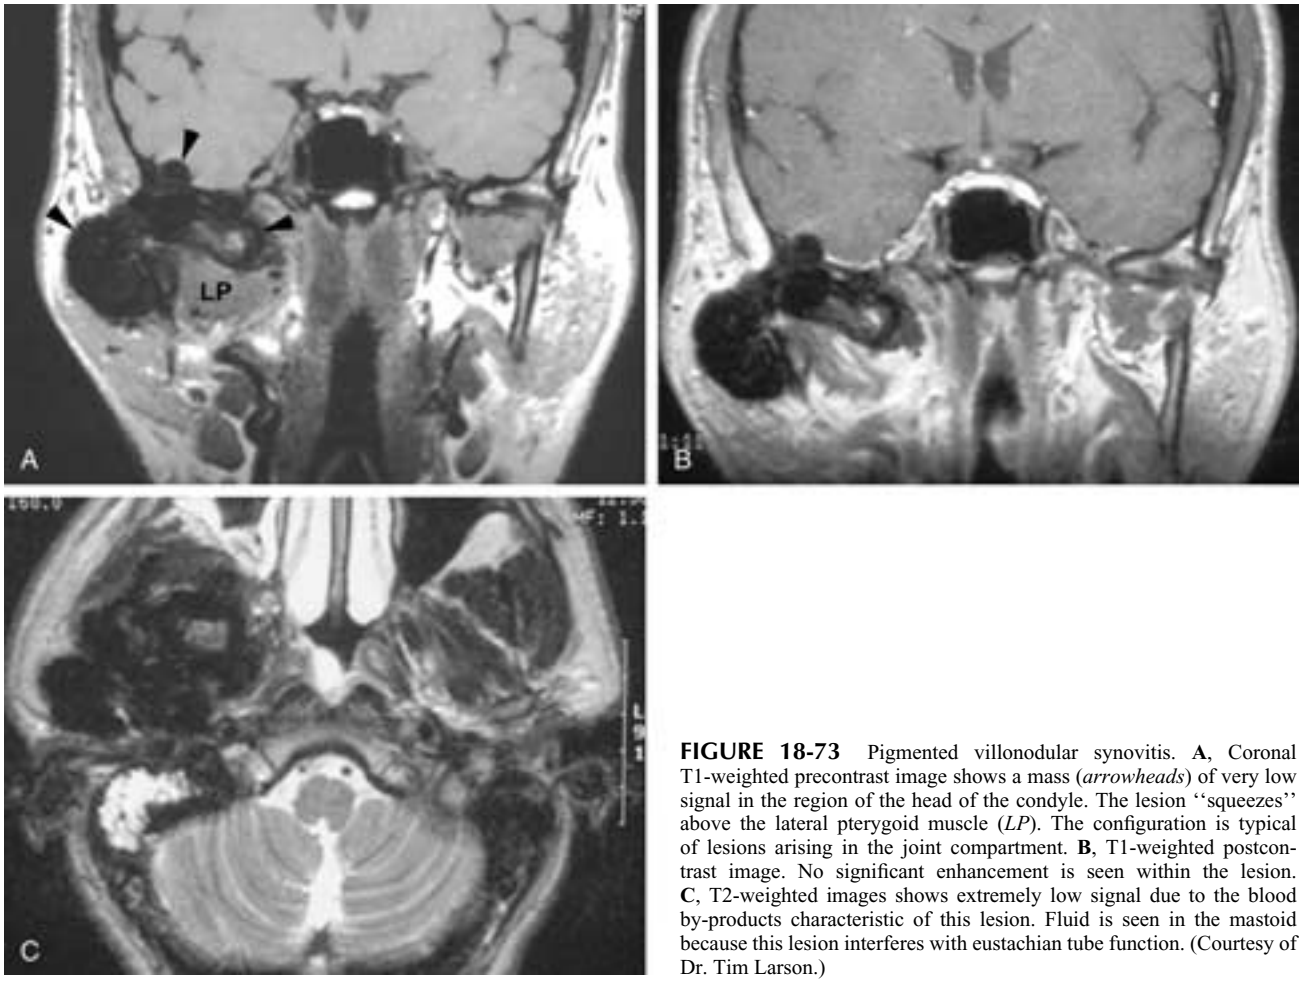

FIGURE 18-73 Pigmented villonodular synovitis. **A**, Coronal T1-weighted precontrast image shows a mass (*arrowheads*) of very low signal in the region of the head of the condyle. The lesion ''squeezes'' above the lateral pterygoid muscle (*LP*). The configuration is typical of lesions arising in the joint compartment. **B**, T1-weighted postcontrast image. No significant enhancement is seen within the lesion. **C**, T2-weighted images shows extremely low signal due to the blood by-products characteristic of this lesion. Fluid is seen in the mastoid because this lesion interferes with eustachian tube function. (Courtesy of Dr. Tim Larson.)

VIEW IMAGE

Synovial Cysts and Simple Bone Cysts

Synovial cysts of the TMJ have been reported but are rare (Fig. 18-77).[150, 151] They present with unilateral pain and possible enlargement of the condyle head, and there can be associated swelling.

Simple bone cysts are most frequently located in the body of the mandible. However, they may occur in the condyle head (Fig. 18-78), and often the remaining joint components are normal.

Rare Lesions and Tumors

Eosinophilic granuloma may also present as a lytic lesion involving the mandibular condyle and ramus (Fig. 18-79). Rarely, tumoral calcinosis has been described involving the joint and contiguous muscles.[152] The calcified lesions are best defined on CT scan.

Chondrosarcoma and synovial cell sarcoma, as well as other sarcomas, can occasionally involve the TMJ. Meningiomas, chondroblastomas, and a variety of other tumors may extend into the joint from the contiguous bone, as can malignancies of the external ear and parotid gland.

Metastatic Disease in the TMJ Region

Fewer than 1% of all tumors metastasize to the maxillofacial area.[153-155] Adenocarcinoma is the most common of all metastatic tumors in the jaw, accounting for 70% of the cases. A review of 115 cases of mandibular metastasis found that 30% were metastases from breast carcinoma, 16% from kidney, 15% from lung, 8% from colon and rectum, 7% from prostate, 6% from thyroid, 5% from stomach, 4% from skin, 3% from testes, and other sites represented less than 1% each. Most metastases are found in the molar and premolar regions of the mandible, and only a few cases of metastasis to the mandibular condyle have been reported. Most cases with metastasis to the TMJ region have presented with TMJ-related symptoms.[154] Lymphoma can also rarely involve the TMJ (Fig. 18-80), and bone regeneration may occur after chemotherapy (Fig. 18-80B).[156]

Arthritides

The TMJ is involved in approximately 50% of patients with rheumatoid diseases such as rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis. Imaging is an important adjunct to the clinical diagnosis and is particularly valuable for follow-up of patients with these diseases. Plain films and panoramic images are standard, but MR imaging may be indicated to evaluate the soft-tissue involvement of these diseases.[157] Morphologically, inflammatory arthritis is characterized by synovial proliferation and secondary erosive changes of the bone (Fig. 18-81). Studies with MR

Copyright © 2003, Mosby, Inc. All rights reserved.

imaging have shown potential for accurate evaluation of the soft-tissue components of the joint (Fig. 18-82).[85, 86] A study indicated the additional value of contrast-enhanced images for defining the area of inflammatory change within the joint and in the periarticular soft tissue (Fig. 18-82B).[157] Only limited experience is available with MR imaging of other inflammatory arthritides such as psoriatic arthritis and ankylosing spondylitis. Gout rarely involves the TMJ.[158] There can be erosion of the condyle and swelling of the tissues contiguous to an acutely painful joint. Rarely, the skull base can be eroded.

Acute Trauma

Plain films, panoramic examinations, or CT may be done for acute trauma to the mandible. Most patients do not come to imaging specifically for the TMJ, but in many patients with condylar neck and mandibular fractures there is also injury to the TMJ. Such TMJ trauma is frequently not recognized until after the acute clinical course. MR imaging may occasionally show fractures and effusions not seen on other imaging studies (Fig. 18-83), and thus MR imaging could be helpful in evaluating patients with acute pain following trauma to the face and jaw despite other negative examinations. The external auditory canal should also be closely examined when a jaw fracture is suspected.

Both CT and MR imaging may be helpful in cases with intracapsular fractures (Fig. 18-84). Although CT may show the positional relationship of the osseous fragments, MR imaging (Fig. 18-84) shows any associated disk abnormality. In a situation where reconstructive surgery is contemplated, 3D reconstructions (Fig. 18-84D) may be helpful to evaluate the positional relationships between the joint components.

Penetrating trauma to the TMJ is relatively rare, but it warrants imaging evaluation. It can cause fracture, hematoma, and dislocations. CT is the preferred method of examination, and it is important to obtain both axial and coronal images (Fig. 18-85).

FIGURE 18-74 Osteochondroma of the mandibular condyle. **A** and **B**, Axial and reconstructed sagittal CT scans show the right condyle (*arrows*) to be two to three times larger than the left condyle. There is also irregular mineralization in this condyle. **C** and **D**, Sagittal and coronal MR images of the same joints show mixed low and high signal from the enlarged parts of the condyle (*curved arrows*). The temporal component is normal. The disk (*arrowheads*) is biconcave and located in a normal superior position. (Courtesy of Dr. Donald Macher, Rochester, New York.)

VIEW IMAGE

FIGURE 18-75 Pseudogout. Coronal CT scan of a patient with chronic TMJ pain and normal disk position on an MR image (not shown). There are subtle calcifications in the joint space (*arrows*). Aspiration showed pyrophosphate crystals.

Coronoid Hyperplasia

Hyperplasia or elongation of the coronoid process of the mandible can mimic symptoms of TMJ internal derangement with limitation of jaw opening. This condition has been extensively described, and a study has indicated that elongation of the coronoid process may occur in up to 5% of patients with TMJ symptoms and limitation of jaw opening.[159–161] If the coronoid process is significantly elongated, it can impact on the zygomatic process of the maxilla, causing limitation of jaw opening. CT scans in the axial or sagittal plane, performed in the closed- and open-mouth positions, are valuable in the imaging assessment of patients with a clinical suspicion of coronoid hyperplasia because they can demonstrate the coronoid impaction on the maxilla (Fig. 18-86). Surgical treatment with removal of the coronoid process usually yields good results.

Congenital Anomalies

Bifid Condyle

Congenital anomalies of the TMJ are relatively rare. The most common congenital anomaly is probably the so-called bifid condyle. This implies a partial or complete separation of the condyle into a lateral and a medial half (Fig. 18-87). This is usually of no clinical significance other than in the rare situation in which surgery should be performed and preoperative knowledge of the morphology is important. The picture of a bifid condyle is characteristic on coronal imaging and should be distinguished from acquired pathologic conditions with remodeling and degenerative joint disease.

Hemifacial Microsomia

The TMJ is affected in other conditions such as hemifacial microsomia with underdevelopment of the TMJ. Frequently, there is a flat articular eminence and a small mandibular condyle (Fig. 18-88). The mastoid typically is underdeveloped, with no aeration. The disk is usually in a normal location in hemifacial microsomia. In advanced cases the entire ramus, condyle, and coronoid process of the mandible are not developed (Fig. 18-89).

Asymmetry of the Mandible

Asymmetry of the mandible is a frequent clinical presentation. The most prominent facial features include a shift of the chin to the short side and prominence of the mandibular angle on the long side. There are several obvious causes of mandibular asymmetry such as trauma with fractures, tumors, and congenital anomalies. In many cases, however, the cause of mandibular asymmetry leading to facial deformities is unclear on physical examination, and imaging assessment may be warranted.[162, 163]

Mandibular asymmetry can result principally from enlargement of the condylar head (condylar hyperplasia) on the long side (Fig. 18-90) or from decreased condyle growth (condylar hypolasia) (Fig. 18-91) or degenerative joint disease on the short side (Fig. 18-92).[163–165] Imaging studies are done to determine the cause of mandibular asymmetry and for treatment planning. The imaging evaluation of mandibular asymmetry is outlined in Box 18-5 on page 1049. Soft-tissue imaging is important, and MR imaging may be performed as well as CT. Condylar hypoplasia is most frequently caused by regressive remodeling secondary to long-standing internal derangement; however, the condyle may have a relatively normal appearance, without evidence of degenerative joint disease. The joint appears to be more sensitive to regressive remodeling if the internal derangement occurs during the growth and development phase. However, mandibular asymmetry and change in occlusion have also been described in adults.

Atrophy of the Muscles of Mastication

Atrophy of the muscles of mastication is occasionally seen in patients who are unable to open their mouths. These atrophic changes in the muscles are most frequently secondary to trauma or orthognathic surgery.[88, 166] Less often, they may occur secondary to a tumor (or tumor surgery) affecting the mandidular nerve at the skull base. On MR imaging the atrophic changes of the muscles of mastication are usually reflected as fatty replacement.

Following orthognathic surgery, there is frequently asymptomatic muscle atrophy.[166] Occasionally, this is associated with chewing difficulties and fatigue in the jaw

muscles; in these cases, MR imaging is the best imaging modality. Electromyography may be of some value when asymmetric recordings of the left and right sides can be documented.

MISCELLANEOUS IMAGING

Radionuclide Imaging

Studies have suggested that radionuclide imaging of the TMJ (Fig. 18-93), using conventional skeletal imaging techniques, may be a valuable screening test for osseous disease.[167, 168] The technique can be performed easily, and the radiation dose to the patient is low.[1] An advantage of the technique is that conditions outside the joint also may be easily detected. Radionuclide imaging has not gained popularity for TMJ imaging. This is probably because it is nonspecific, and frequently a second imaging modality is needed to determine the nature of the problem and to form a treatment plan.

Thin-Section MR Imaging

There is continuous ongoing development in MR imaging technology. The signal-to-noise ratio and soft-tissue and spatial resolution are improved each time MR scanners are upgraded. This means that the image quality can be expected to continue to improve, and experimental MR images with improved spatial and soft-tissue resolution (Fig. 18-94) may soon be available commercially. Figure 18-94 was obtained on an autopsy TMJ specimen. It shows significantly improved spatial and soft-tissue resolution because of thinner slice thickness and a smaller field of view. In this image the trabecular pattern of the condyle can be clearly identified, and the perforation of the disk and the osteophyte of the condyle, protruding into the perforation, can be seen with exquisite detail.

Dynamic MR Imaging

The time needed to acquire an image is also rapidly decreasing, and within the next few years, one may be able

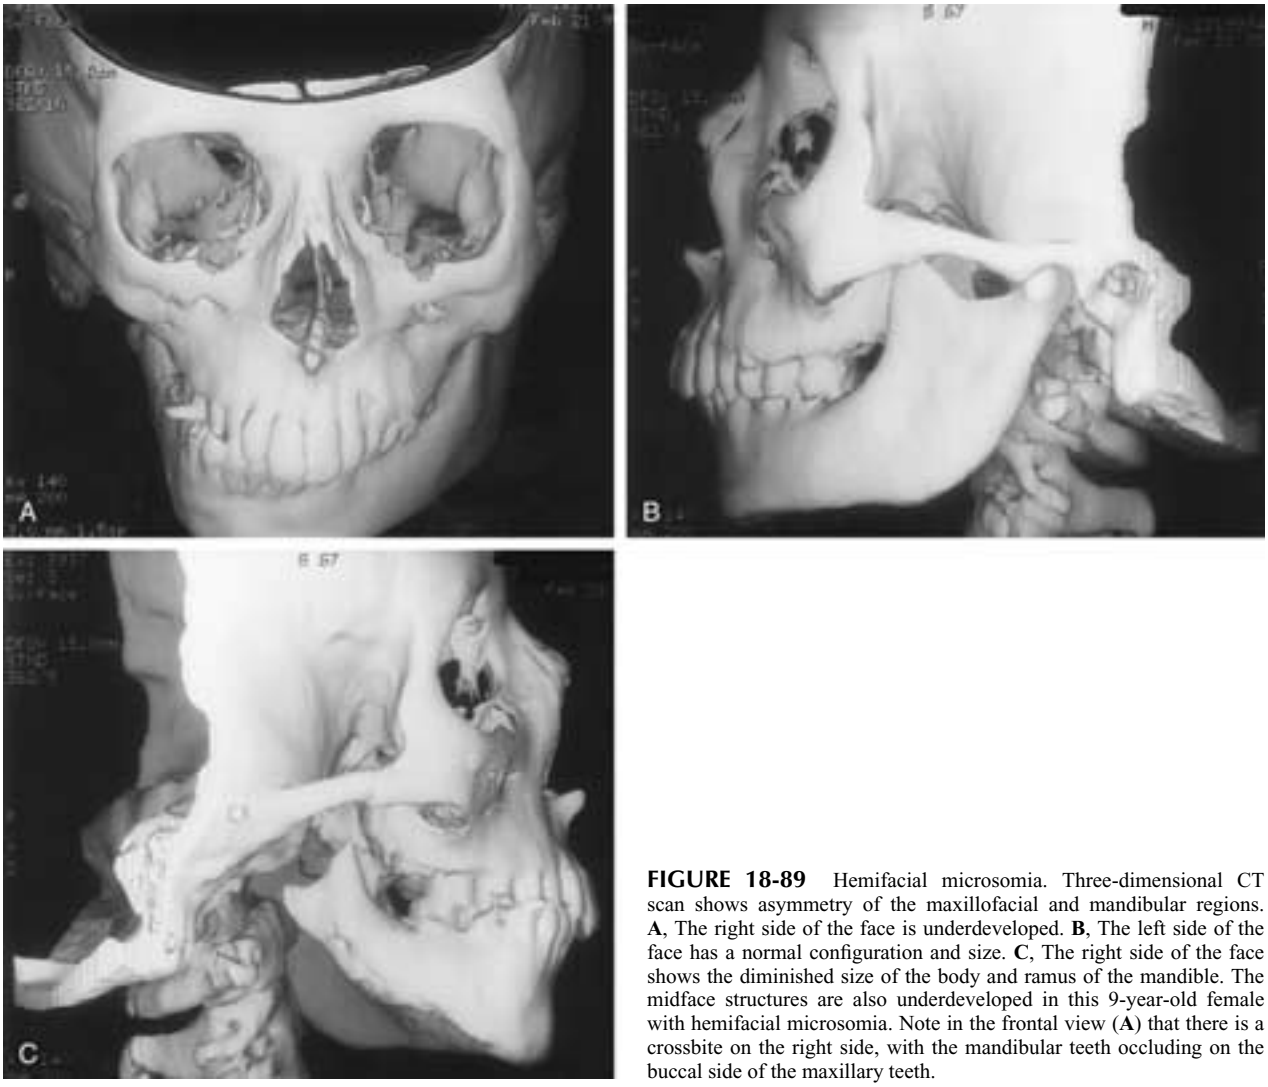

FIGURE 18-89 Hemifacial microsomia. Three-dimensional CT scan shows asymmetry of the maxillofacial and mandibular regions. **A**, The right side of the face is underdeveloped. **B**, The left side of the face has a normal configuration and size. **C**, The right side of the face shows the diminished size of the body and ramus of the mandible. The midface structures are also underdeveloped in this 9-year-old female with hemifacial microsomia. Note in the frontal view (**A**) that there is a crossbite on the right side, with the mandibular teeth occluding on the buccal side of the maxillary teeth.

to obtain real-time dynamic MR images. This will make possible the study of joint dynamics without injection of contrast medium or a local anesthetic. Pseudodynamic imaging with magnetic resonance is possible today, but its value for diagnostic work is not fully understood.[169] Multiple images are collected with the mouth opened to different widths, and the images are rapidly viewed on a *cine loop*. This creates the illusion of a real-time examination even though the images were acquired at separate points in time. However, the position of the disk can be followed, and the snapping of the condyle over the back of the disk can be appreciated.

BOX 18-5

IMAGING STRATEGY FOR PATIENTS WITH MANDIBULAR ASYMMETRY

1. Lateral and anterior posterior cephalograms
2. Lateral tomograms of TMJs, including entire mandibular ramus
3. MR imaging or arthrography of both left and right TMJs

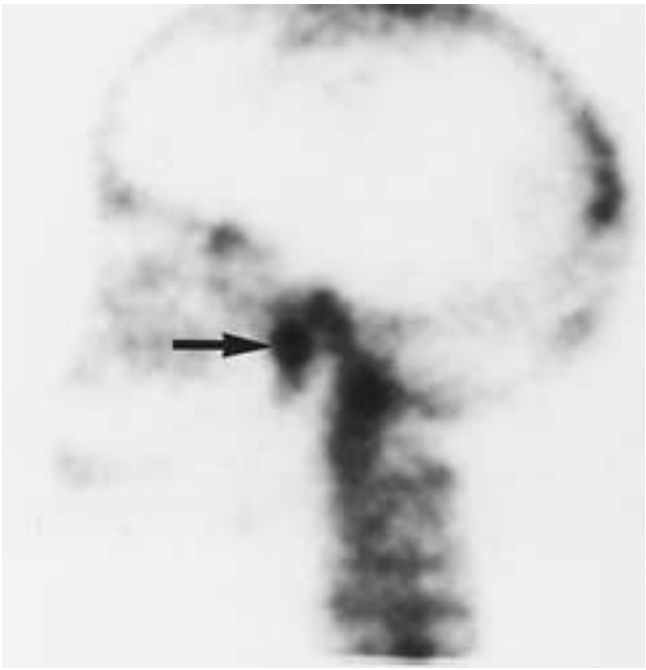

FIGURE 18-93 Radionuclide imaging of a patient with condylar hyperplasia of the left TMJ (*arrow*).

FIGURE 18-94 High-resolution MR image. This experimental MR image was obtained with a slice thickness of 1.5 mm and a field of view of 4 cm. The perforation of the disk (between the *long arrows*) and the osteophyte of the condyle filling the perforation are well visualized. The disk (*d*) is indicated for orientation.

MR Spectroscopy

The third area that will probably develop into a more useful clinical tool is MR spectroscopy. This may be helpful in evaluating metabolic and biochemical changes in the joints and muscles. Previous reports have suggested abnormalities of lactate accumulation in the intervertebral peridiskal tissues of the spine in the presence of degeneration and herniation.[170] MR spectroscopy has also been applied to experimental situations and appears capable of showing changes in areas of inflammation.[171]

SECTION ONE

EMBRYOLOGY AND ANATOMY*

EMBRYOLOGY AND DEVELOPMENTAL ANATOMY

Each of the organs of special sense has a fascinating phylogeny. However, none surpasses the ear in demonstrating the resourcefulness and richness of invention of a biologic system in making adaptive modifications to deal successfully with a changing environment. The ear began as an organ of balance. In the fish of 350 million years ago it existed as a fluid-filled pocket, sunk beneath the surface of the skin on either side of the head. The pocket communicated directly with the ocean water in which the ancient fish swam, providing a mechanism whereby the fish could sense its orientation in the sea. It is physically possible for such a structure to be sensitive to low-frequency vibrations transmitted through the water, and indeed such was likely the case. Hearing nonetheless was incidental, if not accidental, to a structure primarily developed to provide balance.

By the time evolution produced creatures that existed on land, the vestibular system had become much more highly developed. But in so doing, it lost its continuity with the external environment, becoming deeply encased and sealed off within the base of the skull. However, for the creatures to become successful land dwellers, perception of sound had become important to survival. The economy of nature prevailed. Connection between the external environment and the inner ear was reestablished, and the middle and external ears evolved. Concurrently, the hearing portion of the inner ear structure became much more highly specialized (Fig. 19-1).

The following is the story of the development of the ear as we know it. It bears great relevance to the understanding of congenital anomalies, malformations, anatomic variations, and the normal state of the ear.

Streeter provides the definitive account of the embryologic development of the inner ear.[1, 2] Numerous other investigators also studied the development of the ear in the twentieth and previous centuries, but the most complete single source of information relating to development of all portions of the temporal bone remains in Bast and Anson's *The Temporal Bone and Ear*.[3] Shambaugh and Glasscock present the essence of their work in abbreviated form in *Surgery of the Ear*.[4] Iurato presents an even more concise precis in *Submicroscopic Structure of the Inner Ear*.[5]

Inner Ear

The development of the inner ear may be considered in terms of the following three structures: (1) endolymphatic (otic or membranous) labyrinth, (2) perilymphatic (periotic) labyrinth, and (3) bony labyrinth.

Endolymphatic Labyrinth

Inner ear formation commences when the embryo is only about 2 mm in length (crown to rump). A plate-like thickening of neuroectoderm on either side of the head forms midway alongside the hindbrain; this is called the otic placode. It quickly invaginates to form the otic pit. Soon the pit has deepened and narrowed, its lips have fused to form the otocyst (otic vesicle), and it has descended away from its surface ectodermal origin.

The otocyst is fluid-filled and ectoderm-lined and constitutes the primitive endolymphatic (otic), or membranous, labyrinth. The otocyst comes to lie opposite the fifth neuromere and is in contact rostrally with the facial-acoustic primordium, the precursor of the seventh and eighth nerves. Accompanied by these neural cells, the cyst then migrates to the developing skull base.

By the time the embryo is 6 to 7 mm long, the otocyst has elongated and started to divide into two main sections, the longer utriculosaccular portion and the smaller endolymphatic portion that arises at the point on the otocyst wall that originally joined the neuroectoderm. The utricle and semicircular canals differentiate from the posterolateral aspect of the otocyst, and the saccule and cochlear duct and the communication between the two, the ductus reuniens, arise anteromedially.

By the 9 mm stage, two flattened pouch-like diverticuli project from the otocyst. The superior and posterior semicircular ducts will eventually arise from the pouch at the dorsal margin of the otocyst, while the lateral semicircular duct differentiates from the more lateral outpouching. In the 12 to 15 mm stages, the central portions of the walls of these pouches pinch inward and fuse. Thus each disk-like pouch changes into a ring. Initially, a thin plate representing the pinched-in epithelium crosses the central portion, and the canal lumen remains at the periphery of each pouch. The central epithelial plates eventually break down, leaving only the semicircular canals. The region where these canals join the otocyst becomes the utricle.

The saccule originates from the anteromedial portion of the otocyst. By the 7 to 8 mm stage (3½ to 4 weeks' gestation) the future cochlea is appearing in the form of the primordial cochlear pouch, which develops as an evagination of the saccule (Fig. 19-2). By the 9 mm stage the duct is elongated and beginning to coil; by about 10 weeks (30 mm), it has formed two and a half turns.

Later, the communication between the cochlear duct and the saccule narrows, forming the ductus reuniens. Similarly, parts of the utricle and saccule become constricted to form the utricular duct and the shorter saccular duct, which contribute to the final form of the endolymphatic duct. The major portion of the endolymphatic duct also forms as folds pinch off a portion of the otocyst.

The membranous labyrinth is surrounded by mesenchyme, which differentiates into cartilage that envelops the entire labyrinth. The membranous labyrinth enlarges within its cartilaginous encasement until midterm, by which time it has reached its complicated adult form.

The surrounding cartilaginous otic capsule then ossifies.

VIEW IMAGE

FIGURE 19-1 Comparative embryology of the ear. **A**, In a shark the otocyst is in communication with circumambient water. **B**, Human endolymph contained within the membranous labyrinth is surrounded by another fluid, perilymph. The aqueous system of human progenitors is restored in this way, and the equilibratory function of the inner ear is maintained. **C**, The auditory function, which is subserved by a wave-transmitting system, is brought about in humans by conversion of the branchial arch apparatus of sharks. (Modified from Anson B, Harper D, Winch T. The vestibular and cochlear aqueducts: developmental and adult anatomy of their contents and parietes. Third Symposium on the Role of the Vestibular Organs in Space Exploration. NASA SP 1967;152:125.)

With the exception of the endolymphatic duct and sac, no further growth of these structures occurs during the lifetime of the individual. The endolymphatic duct and sac are the earliest appendages of the otic vesicle to appear. However, unlike the rest of the membranous labyrinth, which reaches adult shape and size by midterm, the duct and sac continue to change throughout infancy and childhood, achieving their adult configuration after puberty. At full adulthood, the endolymphatic sac is three times larger than it is at birth. Its function is discussed later.

The labyrinth reaches its mature anatomic configuration by approximately 6 to 7 months of fetal age, when the membranous labyrinth is completely developed. The formation of its sensory end organs parallels this development and appears in the utricle and saccule first, then within the semicircular ducts, and finally within the cochlea. Differentiation in the cochlear duct goes on at the slowest rate, not being completed until after midterm. It is noteworthy that the cochlea is the last part of the labyrinth to differentiate, and is less stable and more subject to developmental malformations than are the phylogenetically older vestibular end organs.

Perilymphatic (Periotic) Labyrinth

The development of the mesenchyme surrounding the membranous labyrinth is complex.[1, 2] By 6 to 7 weeks (around 20 mm) of fetal age it has become precartilage. At 8 weeks the precartilage changes to an outer zone of true cartilage that forms the otic capsule. The inner zone begins to loosen and vacuolize and forms the perilymphatic space. Fluid-filled cavities appear around the vestibule and cochlear duct and finally surround the semicircular ducts. These spaces all eventually fuse and become confluent, forming a continuous perilymphatic labyrinth containing a delicate matrix composed of arachnoid-like connective tissue. The perilymph circulates within the interstices of the

Copyright © 2003, Mosby, Inc. All rights reserved.

filaments as they traverse the distance between the membranous labyrinth and the endosteum of the otic capsule. This filamentous matrix is present to some degree in all portions of the perilymphatic space except within the scala tympani and scala vestibuli of the cochlea. The absence of filaments within the scalae permits undampened though slight pulsatile movement of the perilymph between the oval and round windows. The kinetic energy of the sound waves is absorbed by the membranes of the cochlear duct and the secondary tympanic membrane of the round window.

The perilymphatic space has three prolongations into the surrounding osseous otic capsule: the cochlear aqueduct (perilymphatic duct), the small fissula ante fenestram, and the fossula postfenestram. The latter two structures are of only remote radiologic interest; however, either or both of them may be involved as a focus of diseased bone in otosclerosis.

The cochlear aqueduct extends from the scala tympani near the round window to the subarachnoid space near the emergence of the glossopharyngeal nerve on the inferior surface of the petrous pyramid. It is described in further detail in the section on Normal Anatomy.

Bony Labyrinth

Ossification of the otic capsule commences only when the cartilage has attained maximum growth and maturity. Once the membranous labyrinth has become encased by enchondral bone, all growth of the inner ear structures ceases and there is no possibility for future expansion of this rigid structure. The enchondral bone formed in the cartilage of the otic capsule is never removed and replaced by haversion bone, that is, there is no remodeling. Along with the ossicles, the otic capsule is unique within the human body. They remain as a primitive, relatively avascular type of bone that is exceptionally hard and poor in its osteogenic response.[6]

Ossification occurs between weeks 16 and 23 of fetal life. Fourteen separate centers are identifiable. No suture lines are visible because ossification begins only after all growth has ceased. The bony otic capsule is complete except for an area over the lateral semicircular canal, a narrow rim of cartilage that remains around the oval window, and the fissula ante fenestram.

The otic capsule is made up of concentric layers of dense enchondral bone, with a thin, uniform layer of endosteal bone being laid down against the endosteal membrane that lines the labyrinth. Outside the enchondral layer, periosteal bone is laid down in parallel lamellae.

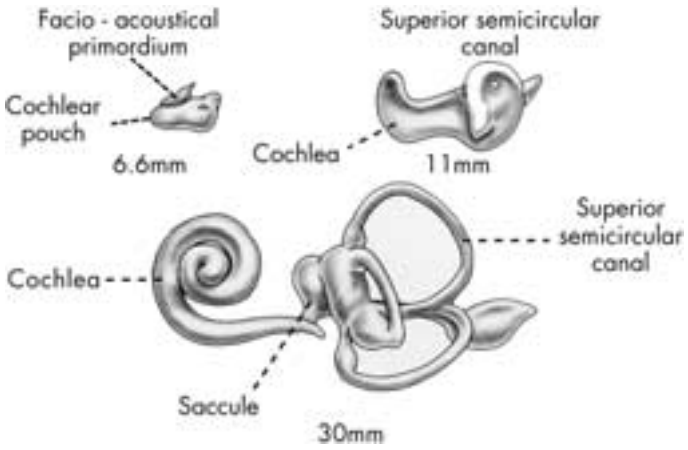
The endosteal layer and the thick middle enchondral layer of the capsule remain relatively inert and unchanged throughout life. In response to infection or trauma the endosteal membrane lining the labyrinth may proliferate, obliterating the lumen of the labyrinth.

The enchondral layer has very limited capability for osteogenic repair, so fractures of the labyrinth may remain completely unhealed except by fibrous union. However, there are also advantages to this poor bone repair. The poor osteogenic response made possible the construction of labyrinthine fenestra that remained permanently open in early operations for stapedial otosclerosis. One of the conditions that prompted the development of stapes prosthesis implantation surgery following stapes mobilization procedures in early otosclerosis surgery was the failure of fractured stapedial crura or footplates to heal.

The periosteal bone of the labyrinthine capsule (i.e., the bone that lies peripheral to the dense middle endochondral bone) continues to be added to by apposition during infancy and up to early adult life. In due course this periosteal bone is removed and replaced by haversian bone. Eventually, pneumatic cells invade most of the periosteal layer of the capsule along with much of the remainder of the temporal bone. As with other periosteal bone, the periosteal layer of the otic capsule reacts readily to infection or trauma with osteogenesis.

As noted, ossification about the entire otic capsule is relatively uniform and complete, with the exception of the following three areas: the area around the oval window, the area of the fissula ante fenestram, and an area over the lateralmost bulge of the lateral semicircular canal.

Ossification in this last region is unique because in early stages it is the same as in the remainder of the otic capsule, with the production of three layers of bone; however, at approximately midterm, the portion covering the lateralmost sweep of the lateral semicircular canal undergoes dissolution. By the thirteenth week, the periosteal layer and varying amounts of the middle enchondral layer have been removed. Eventually there is reconstitution with a varying thickness of the periosteal bone. In some circumstances this reconstitution is (normally) very thin, and for that reason it can appear radiographically as a site of bony dehiscence; this can be misinterpreted as a sign of labyrinthine fistula when it occurs in the presence of cholesteatoma. One should therefore be circumspect and not overinterpret this finding on imaging.



VIEW IMAGE

FIGURE 19-2 Drawing of the developing membranous labyrinth. The 6.6 mm stage shows the beginning of differentiation of the cochlear pouch. The facioacoustical primordium represents the combined seventh and eighth nerves. This primordium separates into individual nerves at the 10 to 11 mm stage. The 11 mm stage shows the cochlear primordium beginning to curl. The shape of the semicircular canals can be identified posteriorly. (Modified from Streeter GL. On the development of the membranous labyrinth and the acoustic and facial nerves in the human embryo. Am J Anat 1907;6:139–167; and Curtin HD, Vignaud J, Bar D. Anomaly of the facial canal in a Mondini malformation with recurrent meningitis. Radiology 1982;144:335–341.)

Outer and Middle Ear

Although it is apparent that the sound-perceiving neurosensory apparatus of the inner ear comes from the neuroectodermal otocyst, the sound-conducting mechanism arises from totally different and widely separated anlages. The sound-conducting mechanisms of the outer and middle ear are derived from the branchial or gill apparatus of the embryo.

By about 4 weeks (6 to 7 mm) of fetal age, several branchial arches separated by external branchial grooves have developed on either side of the head. The first branchial groove deepens to become the primitive external auditory meatus, and the corresponding evagination from the pharynx, the first pharyngeal pouch, grows outward and upward toward it, forming the primitive eustachian tube. For a brief moment in embryologic time, the epithelium of the first branchial groove touches the endoderm of the first pharyngeal pouch at the site of the future tympanic membrane. However, mesoderm soon grows between and separates these two layers, so that the mature tympanic membrane is formed by all three germinal layers.

Over the next 5 fetal months, the first branchial groove contributes to the development of the mature configuration of the external acoustic meatus, the outer, cuticular layer of the tympanic membrane, and the tympanic ring.

The auricle develops from around the first branchial groove from six knob-like outgrowths or hillocks arising from the first and second branchial arches, appearing at the sixth week of embryonic life and fusing by the third month.

The first pharyngeal pouch becomes the eustachian tube and middle ear cavity and its epithelial lining. The cartilages of the first and second branchial arches form the ossicles. The first branchial arch forms the bodies of the malleus and incus; the second branchial arch forms the crura of the stapes, the lenticular process and long crus of the incus, and the manubrium of the malleus. The footplate of the stapes comes from the otic capsule. With further development, the ossicles separate from the remainder of the arch cartilages and join.

The ossicles, similar to the otic capsule and labyrinth, grow only throughout the first half of uterine life and then ossify. Each of these bones ossifies from a single center; the incus appears at 16 weeks, the malleus at 16½ weeks, and the stapes at 18 weeks. The ossicles are formed of enchondral bone that persists for the rest of the individual's life, as does the enchondral layer of the labyrinthine capsule. The malleus and incus remain solid and relatively constant in size and shape. The stapes, however, undergoes a process of erosion and thinning soon after it ossifies. The adult stapes is less bulky and considerably more delicate and fragile than in midfetal life. With this diminution in bulk and weight, exceptional variations in the size, shape, and strength of the adult crura and footplate occur. A normal adult footplate varies from thick and uniform to thin and irregular. It even may be dehiscent in its central portion.

As the ossicles differentiate and ossify, the surrounding mesenchymal connective tissue becomes less dense and less cellular. By 18 to 21 weeks, the tissue filling the space of what is to become the middle ear is very loose, somewhat vacuolated, and mucoid in character. By 22 weeks this vacuolated, mucoid connective tissue gives way to the upward-expanding tympanic epithelium of the first pharyngeal pouch. The latter envelops the ossicles and their tendons and ligaments, investing them with epithelial tissue derived from endoderm. Communication between the pharynx and middle ear is thus established. At maturity, the eustachian tube remains as an anatomic reminder of the upward migration of the first pharyngeal pouch in the formation of the tympanic cavity and communicating spaces.

By 30 weeks, pneumatization of the tympanum proper is almost complete. Pneumatization of the mastoid antrum soon follows and progresses rapidly from weeks 34 to 35, but in the epitympanum it lags and is not completed until the last month of fetal life.

The use of the term *pneumatization* at this stage of development does not imply the actual presence of air in the ear; used in this context, it refers rather to the process of focal dissolution and displacement of mesenchymal connective tissue, with eventual formation of the space that comes to be lined by an advancing layer of endodermal (respiratory) epithelium arising from the first pharyngeal pouch. This space will become the aerated cavities of the eustachian tube, the middle ear, the antrum, and so on at term. Pneumatization thus comes to refer to the creation of an epithelium-lined space to be aerated later.

Pneumatic Cells of the Temporal Bone

The air cells of the temporal bone develop as outpouchings of the antrum, epitympanum, tympanic cavity, and eustachian tube. Despite tentative epithelial evaginations appearing from the antrum as early as 34 weeks, no significant pneumatic cellular expansion into the remainder of the temporal bone occurs until after birth, with the stimulation caused by the presence of air within the middle ear. The pneumatizing process then goes into a period of high activity, proceeding over several years. The petrous apex frequently shows continued progression of pneumatization into early adult life.

Pneumatization occurs as a result of epithelium-lined projections arising from the lining of the middle ear and its extensions. These evaginations probe the spaces between spicules of new bone that are forming and the spaces created by the degeneration of bone marrow into a loose connective tissue stroma. The air cells will invade bone only after the marrow has been converted into a loose mesenchymal tissue. Wittmaack suggests that the presence of middle ear infections in infancy causes the embryonic subepithelial connective tissue to fibrose; this prevents its condensation and thinning and impedes the progress of the advancing fingers of evaginating pneumatic cells.[7] This would explain pneumatization arrest following otitis media in infants and children.

Neonatal Temporal Bone

At birth the anatomic portions of the hearing and vestibular system are virtually fully developed, with the exception of the formation of the osseous portion of the external acoustic canal. Even the internal acoustic canal

FIGURE 19-3 Coronal CT scan, late fetal stage. **A**, The position of the temporal bone in the inferolateral part of the skull is identified. Although the malleus and cochlea are well formed, there is no bony external auditory canal. The tympanic membrane faces inferolaterally the undersurface of the skull. **B**, The ossicular chain is well formed and has achieved its adult size and shape. No significant mastoid process is identified. (Courtesy of the Louis E. Etter Collection.)

(which is not part of the bony labyrinth but is by common clinical practice considered part of the inner ear because of its juxtaposition and functional relationship to the labyrinth) has a nearly adult vertical dimension and will grow probably no more than 1 mm in height during the remainder of the individual's life. (The length of the internal acoustic canal, however, will increase substantially during childhood.)

Shambaugh and Glasscock emphasize that the remainder of the neonatal temporal bone, however, is small and differs from the adult bone both in shape and in position, occupying the inferolateral surface of the skull rather than the lateral aspect, as in mature individuals (Fig. 19-3).[4] They note that, as viewed from the side, the infant temporal bone consists of a large squamous portion, a diminutive tympanic portion, and virtually no mastoid. Whereas in the adult the mastoid lies posterior to the tympanic ring, in the child the petrous portion lies behind the tympanic ring and below the squamous portion.

Formation of the Mastoid Process

The mastoid process begins to develop during the second year of life, with downward growth of the squamous portion and partially as a result of extensions of the petrous portion. These two parts of the mastoid process come together at the petrosquamous suture line. Air cells grow down from the antrum vertically toward the mastoid tip and laterally and radially into the squamous portion. A dividing bridge of bone separating these two cell tracks (at the junction of the petrous and mastoid ossifications) is known as Koerner's septum. This is visible radiographically as a pointed, bony spicule originating from the antral roof and directed obliquely downward.

With further maturation of the mastoid, the thin, incomplete infantile ring that constitutes the tympanic portion of the bone grows laterally and inferiorly to form the osseous portion of the previously completely cartilaginous external auditory canal. Two suture lines are formed: the tympanosquamous suture arising in the anterosuperior meatal wall and the posteriorly positioned tympanomastoid suture.

NORMAL ANATOMY

The anatomy of the temporal bone is complex and in many circumstances confusing (Figs. 19-4 and 19-5; see also the figures in Section Two of this chapter). Part of the complexity has to do with 350 million years of evolutionary modification of this organ, and part has to do with unfortunate anatomic terminology, ambiguity, imprecision, and redundancy that have become fixed in scientific nomenclature. The following section is a compendium gathered from many anatomic sources.[3, 5, 6, 8–13]

Temporal Bone

The temporal bones are situated at the sides and base of the skull. Each consists of the following five parts: squamous, mastoid, petrous, tympanic, and styloid process.

Squamous Portion

The squamous portion forms the anterolateral and upper part of the bone; it is shell-like and thin. The external surface is smooth and convex, giving attachment to the temporalis muscle; it forms part of the wall of the temporal fossa. A gently arching zygomatic process arises from the lower portion of the squama and is directed anteriorly. Its lateral surface is convex and lies directly beneath the skin and subcutaneous tissue. The medial surface of the zygomatic process is concave and serves as the origin of the masseter muscle. The anterior end of the zygomatic process articulates with the zygomatic bone. The posterior portion of the zygomatic process is divided into an anterior and a

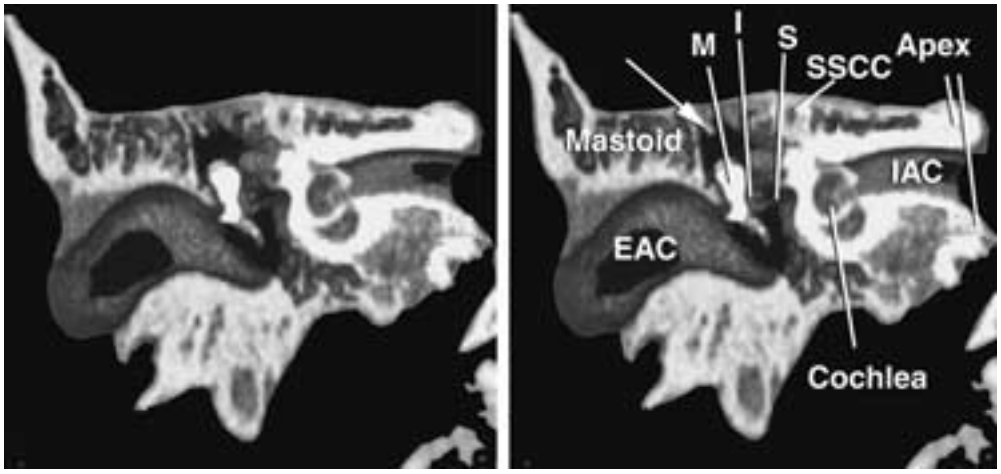
FIGURE 19-4 Diagram of the right temporal bone as viewed from superiorly showing the gross relationships of the key structures to one another. The axis of the temporal bone would run from the upper left-hand corner to the lower right. Note that the first segment (1) of the seventh nerve, the axis of the cochlea, and the superior semicircular canal are perpendicular to this plane, while the second segment (2) of the facial nerve and the posterior semicircular canal are parallel to this plane.

posterior root. The posterior root lies above the external auditory canal and becomes continuous with the temporal line posterior to the external auditory canal. The anterior root becomes the articular tubercle of the condylar (glenoid or mandibular) fossa. The condylar fossa is bound posteriorly to the anterior surface of the tympanic bone.

The mandibular fossa is cleaved in the coronal plane by the tympanosquamous suture laterally and by that suture's inward extension, the petrotympanic (Glaserian) fissure, medially. The portion of the condylar fossa anterior to the fissure is the articular portion of the joint; the portion posterior to the Glaserian fissure is the nonarticular portion.



VIEW IMAGE

FIGURE 19-5 Thick coronal CT image (frontal view) showing the relationship of the structures within the temporal bone. The external ear including the external auditory canal (*EAC*) forms the lateral part of the ear. The middle ear contains the ossicles (*M* = malleus; *I* = incus; *S* = stapes). The labyrinth, situated central to the middle ear, includes the cochlea, vestibule, and semicircular canals (*SSCC* = superior semicircular canal). The more medial portion of the temporal bone includes the petrous apex and the transiting internal auditory canal (*IAC*). The mastoid is an extension from the antrum, which is an extension from the middle ear. The mastoid air cells can extend to the most lateral plate of the temporal bone. Koerner's septum (*arrow*).

Copyright © 2003, Mosby, Inc. All rights reserved.

The internal surface of the squama is concave and irregular. Meningeal vessels groove the inner surface. The superior border articulates with the parietal bone, and the anteroinferior border articulates with the greater wing of the sphenoid.

Mastoid Portion

The mastoid portion has a rough outer surface and serves as the origin of a portion of the occipital and posterior auricular muscles. In the adult the mastoid portion is continued inferiorly into a conical projection, the mastoid process. This process gives attachment to the sternocleidomastoid, splenius capitis, and longissimus capitis muscles. On the medial side of the process is a deep groove, the mastoid notch or digastric groove, for the attachment of the posterior belly of the digastric muscle. Medial to this is a shallow furrow, the occipital groove, that lodges the occipital artery.

The inner or intracranial surface of the mastoid presents a deeper groove, the sigmoid sulcus, that lodges part of the transverse sinus.

The posterior superior border is serrated and articulates with the parietal bone. The posterior border, similarly serrated, articulates with the inferior border of the occipital bone. Anteriorly and above, the mastoid portion is fused with the descending process of the temporal squama; below, it enters into the formation of the external acoustic meatus and the tympanic cavity.

The mastoid process is hollowed to form a number of spaces, the mastoid cells, that vary greatly in size and number. In the upper and anterior part of the process, these cells are large and irregular, toward the middle part they diminish in size, and those in the apex of the process frequently are small. In addition to these cells a large, irregular cavity, the tympanic antrum, occurs and is situated at the upper and anterior part of the mastoid portion of the bone. The antrum communicates with the epitympanum (attic), situated anteroinferiorly and medially by way of the narrow channel, the additus ad antrum.

Petrous Portion

The petrous pyramid is wedged in at the base of the skull between the sphenoid bone anteriorly and the occipital bone posteriorly. Its apex is directed medially, forward, and slightly upward. It contains the inner ear.

The petrous portion resembles a toppled three-sided pyramid lying on the flat surface of one of its sides. The base of this pyramid is laterally positioned and fused with the internal surfaces of the squamous and mastoid portions of the temporal bone. The apex points medially and forward (at approximately a 45° angle with the coronal and sagittal planes) and is inserted into the angular interval between the posterior border of the greater wing of the sphenoid bone and the basilar part of the occipital bone. The anterior (middle fossa) face of the petrous pyramid has a more horizontal orientation and is ''longer'' than the posterior surface, which is relatively vertical and ''shorter.''

The surface of the petrous portion often considered the superior surface actually faces somewhat anteriorly and so is more accurately called the anterior face. This anterior face forms the posterior limit of the floor of the middle cranial fossa and is continuous laterally with the inner surface of the squamous portion; it is united at these edges by the petrosquamous suture. Its surfaces are somewhat irregular and marked by depressions for convolutions of the brain and by a shallow depression medially for the reception of the semilunar ganglion (Meckel's cave) of the fifth cranial nerve. The arcuate eminence, which marks the approximate site of the underlying superior semicircular canal, is near its midportion. Anterior and slightly lateral to this eminence is a depression that marks the position of the tympanic cavity. The layer of bone that separates the tympanic and cranial cavities is usually very thin and is known as the tegmen tympani. Two small grooves cross this surface of the temporal bone, passing from the area of the foramen spinosum and foramen lacerum laterally and posteriorly to a small opening called the facial hiatus. The facial hiatus is a small opening or defect that transmits the greater superficial petrosal nerve and the petrosal branch of the middle meningeal artery. This small opening marks the location of the geniculate ganglion and first genu or turn of the facial nerve. The amount of bone ''closing'' the facial hiatus is variable. In some cases, the facial nerve and geniculate ganglion are positioned just below the dura of the middle fossa and lack a significant bony covering.

The posterior face (surface) of the petrous pyramid forms the anterior bony limit of the posterior fossa and is continuous with the inner surface of the mastoid portion of the temporal bone at the petromastoid suture. To reiterate, this face has a more vertical orientation than the anterior surface. Near the center of this surface is the opening to the internal auditory (acoustic) canal (meatus), which transmits the seventh and eighth cranial nerves, the nervus intermedius, and the internal auditory artery. The opening of the internal auditory canal is known as the porus acusticus. The lateral end of the internal auditory canal is closed by a vertical plate of bone that separates the fundus of the canal from the vestibule. This bony separation has many perforations allowing passage of nerve filaments. These regions are called the cribriform areas. The fundus is divided by a transverse (axially oriented) crest of bone, the crista falciformis, into a smaller upper and a larger lower compartment. The crista, which arises anteriorly, continues for a variable distance along the anterior wall of the internal auditory canal. The upper compartment occupies about 40% and the lower about 60% of the vertical dimension of the canal. In the upper compartment the facial nerve (VII) lies anteriorly, and the superior vestibular division of cranial nerve VIII lies posteriorly. The branches of the latter go to the utricle and the superior and lateral semicircular canals. A thin vertical crest of bone separates the lateral portion of this upper compartment into its anterior and posterior portions. This crest is referred to as Bill's bar. The bony bar separates the aperture for the exit of the facial nerve anteriorly from the small openings for the branches of the superior vestibular nerve posteriorly. A small channel along the posterolateral aspect of the vertical crest may be seen carrying a small branch of the vestibular nerve passing toward the ampulated end of the superior semicircular canal. In the compartment beneath the crista falciformis there are three sets of foramina. Anteriorly, a set of perforations is arranged spirally to accommodate the cochlear division of the eighth cranial nerve. Posteriorly, branches of the inferior division of the vestibular nerve take their exit, one set of

Copyright © 2003, Mosby, Inc. All rights reserved.

foramina leading to the saccule and the remainder leading to the posterior semicircular canal. The nerve to the posterior semicircular canal follows a small channel called the singular or singulate canal.

On the posterior surface of the petrous bone, slightly posteroinferior to the internal acoustic meatus, is a small slit that leads to the vestibular aqueduct. The aqueduct transmits the endolymphatic duct and sac. The endolymphatic sac fills most of the bony aqueduct and protrudes beneath its lower margin. Thus the sac has an intraosseous part, within the aqueduct, and an extraosseous part lying between the layers of the dura of the posterior fossa. The sac is not a single cavity but rather a system of connected channels.

The inferior face (surface) of the petrous pyramid is a rough, irregular surface and forms part of the exterior of the base of the skull. It furnishes partial attachment for the levator veli palatini and the cartilaginous portion of the eustachian tube. It is pierced anteriorly by the aperture of the carotid canal. Posterior to the entrance of the carotid canal lies the jugular foramen. This aperture has an anteromedial and a posterolateral part. Cranial nerves IX, X, and XI transit the anteromedial part in close association with the inferior petrosal sinus. The sigmoid sinus curves into the posterolateral part. The cochlear aqueduct, which communicates with the basal turn of the cochlea, arcs superiorly and laterally from the notch-like anteromedial portion of the jugular foramen.

Thus, near the midportion of the posterior surface of the petrous portion of the temporal bone, extending roughly in a straight line from cranially to caudally, are the internal auditory canal, the aperture of the cochlear aqueduct, and the jugular fossa.

There are two minute canals that perforate the inferior surface of the petrous portion within or near the jugular fossa. The inferior tympanic canaliculus, which accommodates the tympanic branch of the glossopharyngeal nerve (Jacobson's nerve) and the inferior tympanic artery (from the ascending pharyngeal), lies between the carotid canal and the jugular fossa. The mastoid canaliculus, which serves as entrance for the auricular branch of the vagus nerve (Arnold's nerve), is located within the lateral part of the jugular fossa.

The styloid process originates from the inferior face of the pyramid. The stylomastoid foramen is situated between the downward projections of the mastoid process and the styloid process. This foramen constitutes the terminus of the bony facial nerve canal.

The superior angle (border) of the petrous portion of the temporal bone is grooved for the superior petrosal sinus and gives attachment to the tentorium cerebelli. This superior angle, commonly referred to as the petrous ridge, represents the line of the intersection between the anterior and posterior surfaces of the pyramid. The anteromedial extremity of the ridge is notched or scalloped for the reception of the roots of the trigeminal nerve. A small notch marks the position of Dorello's canal, a small dural reflection through which the sixth cranial nerve transits into the cavernous sinus.

The posterior angle of the pyramid is defined by the junction of the lower aspect of the posterior surface with the posterior limits of the inferior surface. From the perspective of the inner surface of the skull within the posterior fossa, the posterior angle is marked by a sulcus on the petrous portion that, along with a corresponding sulcus on the occipital bone, forms the channel for the inferior petrosal sinus. An excavation on the inferior and medial aspect of the posterior surface of the pyramid, in continuity with this sulcus, is known as the jugular fossa. The corresponding depression, in continuity with the sulcus arising from the anterolateral surface of the occipital bone, is known as the jugular notch. These semilunar cavities face one another and together form the jugular foramen. Within the temporal bone, the jugular vein has a dilated portion called the jugular bulb. The jugular bulb rises variably toward the labyrinth and middle ear.

The anterior angle of the pyramid marks the junction between the pyramid and the bones of the anterior floor of the middle cranial fossa. The anterior border is divided into two parts: the medial part, which articulates with the greater wing of the sphenoid, and the lateral portion, which adjoins the squamous part at the petrosquamous suture.

At the angle of the junction of the petrous and squamous portions along the anteromedial margin of the middle ear cavity, there are two (semi) canals placed one above the other, which are separated by a thin plate of bone. This septum is known as the septum canalis musculotubarii (cochleariform process). The upper canal contains the tensor tympani muscle, and the lower canal is the bony portion of the eustachian tube.

Tympanic Portion

The tympanic portion of the temporal bone is a curved plate lying below the squamous portion and in front of the mastoid process. Its posterior surface is somewhat C-shaped and forms the anterior wall, the floor, and the posteroinferior aspect of the bony external auditory canal. At the medial end of the canal is a narrow furrow, the tympanic sulcus, for the attachment of the tympanic membrane. The lateral border of the tympanic portion of the temporal bone is roughened, forming a large part of the margin of the opening of the external auditory canal; this is continuous with the cartilaginous part of the canal. The lateral part of the upper border is fused with the back of the postglenoid tubercle. Its medial extension forms the posterior boundary of the petrotympanic fissure.

There is considerable ambiguity in anatomic descriptions regarding the terms *petrotympanic fissure*, *tympanosquamous fissure*, and *Glaserian fissure*. Many anatomic depictions point unassailably to a junction between the squamous and tympanic portions, labeling the area the *petrotympanic fissure*. This is more easily understood if one recognizes that the tympanosquamous fissure (squamotympanic) is merely the lateral extension of the petrotympanic fissure, and the Glaserian fissure is the medial extension of the petrotympanic fissure. This serves as a passageway for the anterior tympanic branch of the internal maxillary artery. In the most medial extreme portion of the petrotympanic fissure is the small canal for the chorda tympani, the iter chordae anterius (anterior tympanic aperture, canal of Huguier).

The lower border of the tympanic bone encloses the root of the styloid process. Posteriorly the tympanic portion blends with the squamous and mastoid portions, forming the anterior boundary of the tympanomastoid fissure.

Copyright © 2003, Mosby, Inc. All rights reserved.

Styloid Process

The styloid process of the temporal bone averages about 2.5 cm in length and projects downward and forward from the undersurface immediately anterior to the stylomastoid foramen. It gives origin to the stylohyoid ligament and the stylohyoid, stylopharyngeus, and styloglossus muscles.

External Auditory Canal

The walls of the external auditory canal (meatus) are formed laterally of fibrocartilage and medially of bone, and both parts are lined by skin reflected inward. The osseous portion of the meatus, which makes up slightly more than half of the canal, is a tunnel through the temporal bone. The bony canal is about 16 mm long and is directed inward, forward, and downward. On a sagittal scan the canal is oval or elliptical in shape, with its long axis directed downward and slightly backward. The anterior wall, floor, and lower part of the posterior wall are formed by the tympanic component of the temporal bone; the remainder of the posterior wall and the roof arise from the squamous portion of the temporal bone.[11]

The tympanic membrane makes a compound angle with the external acoustic meatus. The inferior border of the tympanic membrane lies closer to the midsagittal plane of the head than does the superior border. Additionally, the anterior border lies closer to the midsagittal plane than does the posterior border. This means that the tympanic membrane is sloping both downward and inward. The posterosuperior wall of the external auditory meatus is about 25 mm long in the adult, and the anteroinferior wall is more than 30 mm.

Vessels and Nerves

The arteries of the external auditory meatus are derived from the external carotid artery through branches from the posterior auricular, superficial temporal, and internal maxillary arteries. The veins and lymphatics connect with those of the auricle. The veins ultimately empty into the internal and external jugular veins and occasionally into the sigmoid sinus by way of mastoid emissary veins.

The lymphatics of the external acoustic canal and auricle empty into all adjacent regional nodes, including the parotid, superficial cervical, and retroauricular groups.

Because the development of the external ear is embryologically complex, the cutaneous innervation is similarly complex and subject to considerable variation. Innervation is derived from the auriculotemporal branch of the mandibular division of the trigeminal nerve and from cutaneous branches of the cervical plexus, primarily the greater auricular nerve from C2 and C3. There are also contributions from sensory fibers originating in the seventh, ninth, and tenth cranial nerves.

Tympanic Membrane

The tympanic membrane is the medial boundary of the external auditory canal, separating the canal from the middle ear. This thin, transparent membrane is somewhat oval in shape. It is slightly broader above than below. Its greatest diameter is approximately 9 to 10 mm. The manubrium or handle of the malleus is attached to the membrane along a line from just caudad to the midpoint of the membrane to a point just inferior to the upper margin. The most caudad point of attachment is pulled slightly medially toward the middle ear. This point is readily identified using an otoscope and is called the umbo. The periphery of the tympanic membrane is a fibrocartilaginous ring that attaches to the tympanic sulcus at the medial end of the external auditory canal. The ring is incomplete superiorly and anteriorly, corresponding to a similar gap in the superior aspect of the tympanic ring called the notch of Rivinus. From the anterior and posterior magins of this notch, thin folds called the anterior and posterior mallear (malleolar) folds extend to the lateral process of the malleus. These two folds in the membrane along with the superior rim of the canal create a triangular, thin, lax zone, the pars flaccida, in the superior-anterior portion of the tympanic membrane. This lies immediately under the scutum, the most medial point of the roof of the external auditory canal (see below). The remaining tympanic membrane is taut and is referred to as the pars tensa.

Middle Ear

The middle ear, or tympanic cavity, is an irregular, laterally compressed space within the temporal bone. It is filled with air conveyed to it from the nasopharynx via the eustachian tube. The middle ear is traversed by the ossicular chain connecting the lateral and medial walls. The ossicles both transmit and amplify the vibrations incident on the tympanic membrane across the cavity to the inner ear.

The tympanic cavity consists of three parts: the tympanic cavity proper (or mesotympanum) opposite the tympanic membrane, the attic (or epitympanic recess or epitympanum) above (cranial to) the level of the membrane, and the hypotympanum, a variable inferior and medial extension occurring below (caudal to) the level of the tympanic membrane.

Shaped more like a cleft than a box, the vertical dimension (including the attic) and the anteroposterior dimension of the cavity are each about 15 mm. The transverse dimensions measure about 6 mm superiorly and 4 mm inferiorly. Opposite the center of the tympanic membrane the transverse dimension may be only about 2 mm. The lateral extent of the cavity is defined by the tympanic membrane or membranous wall, and the medial or labyrinthine wall is formed by the otic capsule. The roof is known as the tegmental wall, and the floor, separated from the jugular fossa by a thin plate of bone, is known as the jugular wall. Anteriorly the space is delimited by the carotid wall and posteriorly by the mastoid wall.

Roof or Tegmental Wall

The tegmen tympani is a plate of bone that arises from the petrous portion of the temporal bone. Its forward prolongation becomes the roof of the canal for the tensor tympani muscle, and its backward continuation forms the roof of the mastoid antrum. The tegmen tympani separates the middle ear cavity from the middle cranial fossa. The lateral margin of the tegmen interdigitates with the squamous portion of the temporal bone at the petrosquamous suture. In children this may be unossified and may allow direct passage of infection

Copyright © 2003, Mosby, Inc. All rights reserved.

from the middle ear to the epidural space of the middle cranial fossa. In adults, veins from the middle ear perforate this suture to end in the petrosquamous sinus (present in about 50% of cases) and the superior petrosal sinus. They may transmit infection directly to the cranial venous sinuses.[10]

Floor or Jugular Wall

The floor or jugular wall of the middle ear cavity lies either at or slightly below the level of the floor of the external auditory meatus and is usually a very thin plate of cortical bone that separates the cavity from the internal jugular vein. If the jugular bulb is particularly small, the floor may be correspondingly thick (occasionally up to 1 cm), and it may contain air cells intervening between the middle ear cavity and the internal jugular vein. The inferior extent of the tympanic cavity below the level of the inferior attachment of the tympanic membrane, along with its medial extension, is known as the hypotympanum.

If the jugular bulb is very large, it may bulge upward into the floor of the tympanic cavity, giving it a convex margin. This bulging reduces the potential size of the hypotympanum. Occasionally the bone may be dehiscent with the jugular bulb present within the hypotympanum.

A small aperture for the passage of the tympanic branch of the glossopharyngeal nerve (Jacobson's nerve) is present between the carotid canal and the jugular plate near the labyrinthine wall.

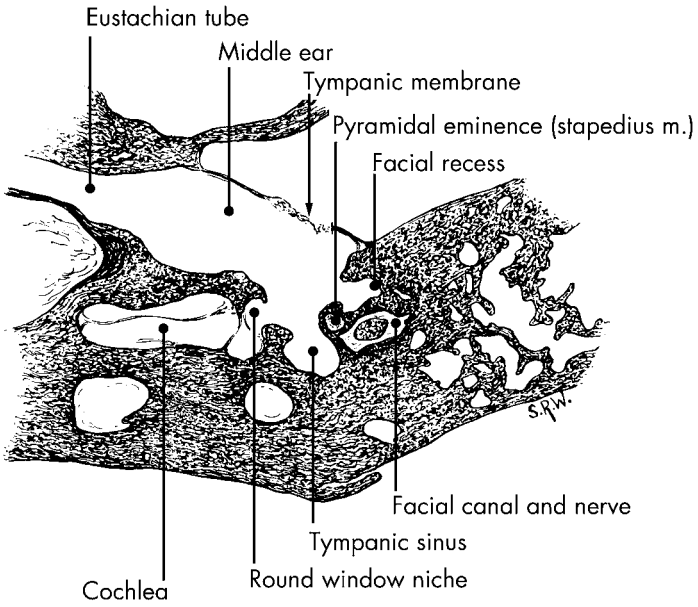


FIGURE 19-6 Relationships of the sinus tympani, facial recess, and facial canal within the posterior wall of the middle ear. Axial section through the temporal bone at the level of the round window niche. These relationships are of paramount importance to the operating surgeon because they affect the surgeon's ability to gain access to diseased tissue. The tympanic sinus may be the site of occult disease. Primary facial nerve pathologic processes may also obliterate these spaces. This minute anatomy is exquisitely defined on axial CT.

VIEW IMAGE

Mastoid or Posterior Wall

The mastoid or posterior wall is wide above and below and presents the additus ad antrum (entrance to the tympanic antrum), the pyramidal eminence, and the incudal fossa. The additus ad antrum is a large, irregular aperture that leads posteriorly from the epitympanic recess to the mastoid antrum. The pyramidal eminence is situated immediately behind (dorsolateral to) the oval window and in front of (ventral or medial to) the vertical (mastoid) portion of the facial canal; it is hollow and contains the origin and belly of the stapedius muscle. Its summit projects forward toward the stapes and is pierced by a small aperture that transmits the tendon of the muscle. The cavity of the pyramidal eminence is prolonged downward and backward in front of or slightly medial to the facial canal and communicates with it by a minute aperture that transmits a twig from the facial nerve to the stapedius muscle.

There are two important recesses in the posterior wall, the sinus tympani and the facial recess (Fig. 19-6). They may be the sites of occult extension of disease within the middle ear, and they are demonstrated well on axial CT scans.

The tympanic sinus is a space that is bounded by the labyrinthine wall medially and by the pyramidal eminence laterally.

The facial recess is bounded by the pyramidal eminence, styloid complex, and facial canal medially and by the bony tympanic annulus laterally. The facial recess is an important surgical landmark when the middle ear cavity is entered via the mastoid approach. Entrance is initially gained into the mesotympanum by enlarging this recess using the facial nerve and chorda tympani as landmarks.

The incudal fossa is a small depression in the lower and posterior portion of the epitympanum. This recess contains the short process of the incus and is the attachment, the posterior ligament of the short process of the incus.

Just lateral and usually slightly inferior to the aperture transmitting the tendon of the stapedius muscle is the aperture for the chorda tympani nerve that is separated from the mastoid portion of the facial nerve by part of the facial recess. The chorda tympani leaves the mastoid part of the facial nerve usually in the lower part of that portion of the facial canal and then turns superiorly to travel up through the canaliculus of the chorda (iter tympani posteriorus). The nerve enters the middle ear cavity, runs lateral to the long process of the incus, medial to the manubrium of the malleus, and then exits the middle ear cavity.

Carotid or Anterior Wall

The carotid or anterior wall is wider above than below and corresponds to the carotid canal, from which it is separated by a thin plate of cortical bone that is perforated by the tympanic branch of the internal carotid artery and by the caroticotympanic nerve. At the upper part of the anterior wall are the orifice of the semicanal for the tensor tympani muscle and the tympanic orifice of the eustachian tube, separated from each other by the septum canalis musculotubarii. These structures run from the tympanic cavity forward and downward to the angle between the squamous and petrous portions of the temporal bone. These channels lie one above the other rather than side by side.

The semicanal for the tensor tympani is the superior and smaller of the two structures; it is cylindrical and lies beneath the tegmen tympani. It extends to the labyrinthine wall of the tympanic cavity and ends immediately above the

Copyright © 2003, Mosby, Inc. All rights reserved.

oval window. In current usage the septum canalis musculotubarii is more commonly known as the cochleariform process (processus cochleariformis). This bony structure forms the lateral wall and floor of the semicanal for the tensor tympani.

Eustachian Tube

The eustachian tube is the lower of the two channels and the one through which the tympanic cavity communicates with the nasopharynx. Its length is about 3.5 cm, and its direction is downward, forward, and medial. It forms an angle of about 45° with the sagittal plane and one of about 30° to 40° with the horizontal plane. Part of the eustachian tube is composed of bone, and part is composed of fibrous tissue and cartilage. The osseous portion is a little more than 1 cm in length. It begins in the carotid wall below the process cochleariformis and, tapering slowly, ends at the angle of the junction of the squamous and petrous portions of the temporal bone. Its most distal end has a serrated margin for the attachment of the cartilaginous portion. The cartilaginous portion is about 2.5 cm in length. The cartilage lies in a groove between the petrous part of the temporal bone and the greater wing of the sphenoid. This groove ends opposite the upper posterior margin of the medial pterygoid plate.

The tube is not of uniform diameter; its narrowest portion (the isthmus) lies at the junction of the bony and cartilaginous portions. It is at its widest diameter at the pharyngeal orifice. The cartilaginous and bony portions of the tube are not in the same vertical plane, the cartilaginous portion being slightly more steeply inclined than the bony portion. The pharyngeal opening of the cartilaginous portion of the eustachian tube is C-shaped, so that the tensor veli palatini, levator veli palatini, and salpingopharyngeus muscles (by attaching to both the medial and lateral sides of the cartilage) can open its lumen maximally during swallowing. This helps ensure that the middle ear and pharyngeal air pressures are equilibrated during swallowing.

Lateral or Membranous Wall

The tympanic cavity extends above the level of the tympanic membrane as the epitympanic recess. The lateral boundary of the tympanic cavity proper therefore is the tympanic membrane, together with the small rim of the temporal bone to which it is attached. The osseous tympanic ring is incomplete superiorly at the notch of Rivinus. Close to this notch are three small apertures: the petrotympanic (Glaserian) fissure and the anterior and posterior tympanic apertures (iter chordae anterius and posterius).

The petrotympanic fissure transmits the anterior tympanic branch of the internal maxillary artery and houses the anterior process of the malleus and its anterior ligament.

The chorda tympani nerve gains entrance to and finds egress from the tympanic cavity by way of the posterior and anterior tympanic apertures, respectively. As the chorda tympani traverses the tympanic cavity, it gives off no branches.

The tympanic membrane is directed obliquely downward and inward, forming an angle of about 50° with the floor of the external acoustic canal and about 15° with the midsagittal plane. The manubrium of the malleus is attached to the medial aspect of the tympanic membrane at its center and pulls the membrane inward; the lateral surface of the membrane therefore appears concave.

Medial or Labyrinthine Wall

The medial wall of the tympanic cavity is the part of the petrous portion of the temporal bone that surrounds the inner ear and separates it from the middle ear cavity.[10] Several bulges and depressions are apparent, reflecting the various contours of the inner ear structures.

Posteriorly and superiorly, in what is the medial wall in the region of the additus, is the prominence produced by the anterior limb of the lateral semicircular canal. Below this and extending more anteriorly is the prominence of the facial canal produced by the bone overlying the intratympanic portion of the facial nerve. Anterior to the prominence of the facial canal is the curving terminus of the septum canalis musculotubarii; this also serves as a landmark for the position of the geniculum of the facial nerve (geniculate ganglion), which lies immediately anterior to the first knee (genu) of the facial nerve.

Immediately below the mesotympanic facial canal is the laterally directed oval window niche, which contains the oval window at its medial terminus. Below the oval window lies the promontory, a convexity that bulges into the tympanic cavity and represents a portion of the otic capsule over the basal turn of the cochlea. Below and behind the back part of the promontory is the round window niche, leading to the round window. Posterior to the promontory is a smooth, bony projection, the subiculum promontorii, which forms the inferior border of the deep depression known as the tympanic sinus. Anterior and inferior to the subiculum lies the round window niche. The opening of the tympanic sinus approximates the junction of the medial and posterior walls of the tympanic cavity. The superior border of the sinus tympani is bounded by another smooth, bony ridge, the ponticulus. The oval window niche lies anterior and superior to the ponticulus.

Epitympanic Recess

That portion of the tympanic cavity extending above the level of the tympanic membrane is known as the epitympanic recess, or attic. This is a chamber having a height about one third that of the entire tympanic cavity; the attic projects slightly more superiorly than does the tympanic membrane. This small portion of the tympanic cavity has as its lateral wall a part of the squamous portion of the temporal bone. The inferior, medially directed, pointed terminus of the lateral attic wall is known as the lateral attic spur or scutum, which is directly above the tympanic membrane.

The attic contains the head of the malleus and the body and short process of the incus. Superiorly the epitympanic recess is bounded by the tegmen tympani; medially by the prominence of the lateral semicircular canal and the prominence of the facial nerve; laterally by the scutum and lateral wall of the attic; and inferiorly by the incudal fossa and the bony surface just behind it. The boundary line between the tympanic cavity proper and the epitympanic recess is marked by the prominence of the facial canal medially, the inferior limit of the incudal fossa inferiorly, and the scutum laterally. The additus ad antrum originates from the posterosuperior aspect of the epitympanic recess.

Copyright © 2003, Mosby, Inc. All rights reserved.

A small recess extends anteriorly from the part of the epitympanum containing the head of the malleus. This anterior epitympanic recess is located just beneath the floor of the middle cranial fossa, lateral to the geniculate turn of the facial nerve and just superior to the cochleariform process and the entrance to the eustachian tube. A small ridge of bone called the cog may partially separate the anterior tympanic recess from the remainder of the epitympanum.

Contents of the Tympanic Cavity

Auditory Ossicles

Three small bones or ossicles span the width of the tympanic cavity: the malleus, the incus, and the stapes. The malleus consists of a head, a neck, the manubrium, and the anterior and lateral processes. The head lies within the epitympanum. The manubrium is attached to the tympanic membrane. The lateral process abuts the tympanic membrane immediately below the pars flaccida. The anterior process is a slender spicule of bone that passes forward and downward into the petrotympanic fissure.

The incus is shaped somewhat like a premolar tooth, with two widely diverging roots that differ in length. The body is somewhat cuboid but compressed transversely. On its anterior surface is a deeply concavoconvex facet that articulates with the head of the malleus. The body of the incus and the head of the malleus are bound to one another by a thin capsular ligament, forming a diarthrodial joint known as the incudomalleolar articulation. The two processes of the incus diverge from one another at nearly right angles. The short crus (short process) projects almost horizontally backward and is attached to the incudal fossa in the lower and posterior portion of the epitympanic recess. The long crus (long process) descends nearly vertically behind and parallel to the manubrium of the malleus and bends medially to end in a rounded projection, the lenticular process, which is tipped with cartilage and articulates with the head of the stapes. This is also a diarthrodial joint and is called the incudostapedial articulation.

From its articulation with the incus, the stapes passes almost horizontally (but slightly cephalad) across the tympanic cavity to meet the wall of the labyrinth at the oval window. The stapes resembles a stirrup and consists of a head, a neck, two crura, and a base. The head has a depression covered by cartilage that articulates with the lenticular process of the incus. The neck is the constricted part of the bone succeeding the head, and its posterior aspect gives insertion to the tendon of the stapedius muscle. The anterior and posterior crura diverge from the neck and are connected at their ends to the flattened oval plate known as the *base*, which forms the footplate of the stapes and is fixed to the margin of the oval window by the annular ligament. The anterior crus is shorter and less curved than the posterior one. The edge of the stapedial base is covered with cartilage, as is the rim of the oval window; the junction thereof constitutes the tympanostapedial syndesmosis.

In summary, the head of the malleus and the body and short process of the incus lie above the level of the scutum, or lateral attic spur, in the epitympanum or attic. The neck of the malleus and the junction of the body and the long process of the incus lie at the level of the scutum, or the junction of the epitympanum and mesotympanum. The manubrium of the malleus and the long process of the incus lie opposite the tympanic membrane in the mesotympanum or main middle ear cavity.

Ligaments

The ossicles are connected with the walls of the tympanic cavity by ligaments, three for the malleus and one each for the incus and stapes.

The anterior ligament goes from the neck of the malleus just above the anterior process to the carotid wall near the petrotympanic fissure. The superior ligament descends from the roof of the epitympanic recess to the head of the malleus. The lateral ligament goes from the posterior part of the notch of Rivinus to the head of the malleus.

The posterior ligament of the incus is a short, thick band connecting the neck and end of the short crus to the posterior wall of the incudal fossa.

The annular ligament of the base of the stapes was described previously. It represents the fibrous ring that encircles the base of the stapes and attaches to the margin of the oval window.

Muscles

The muscles of the tympanic cavity already have been alluded to; one each arises from the anterior and posterior walls.

The tensor tympani, the larger muscle, is contained in the bony canal above the osseous portion of the eustachian tube, from which it is separated by the processus cochleariformis. It passes backward through the canal and ends in a slender tendon that enters the tympanic cavity; it makes a sharp bend around the terminus of the process cochleariformis and is inserted into the neck of the malleus. The tensor tympani is supplied by a branch of the mandibular nerve that passes through the otic ganglion.

The stapedius muscle rises from the walls of the conical cavity hollowed out of the interior of the pyramidal eminence. Its tendon emerges from the orifice at the apex of the pyramidal eminence, extends forward, and inserts into the posterior surface of the neck of the stapes. It is supplied by a branch of the facial nerve.

By their actions, both the tensor tympani and stapedius muscles reduce the efficiency of the sound-conducting mechanism. Both dampen the vibration of the ossicular chain. The tensor tympani accomplishes this by increasing the tension of the tympanic membrane and thereby diminishing the amplitude of excursion of the malleus. The stapedius muscle exerts its action by pulling the head of the stapes backward, which causes the base of the bone to rotate on a vertical axis drawn through its own center. The posterior part of the base is pressed inward toward the vestibule, and the forward portion is withdrawn from it. This reduces the amount of area effectively transmitting the vibration at the footplate and diminishes the mechanical advantage of the lever mechanism. Both of these muscles therefore serve to protect the inner ear from excessive amplitude oscillations of the footplate of the stapes when there is a loud noise. This protective reflex is invoked with low-frequency vibration only and is most effective at frequencies under 5000 Hz.

Nerves and Vessels

The nerves of the middle ear cavity are represented by the tympanic plexus, which lies on the cochlear promontory under the mucosa, within grooves or canals in the bone. This plexus is formed chiefly by the tympanic branch (nerve of Jacobson) of the ninth cranial nerve, but is reinforced by one or more caroticotympanic nerves derived from the internal carotid sympathetic plexus. The facial nerve also makes a minor contribution to the tympanic plexus. These fibers are mostly parasympathetic secretomotor fibers. The tympanic branch of cranial nerve IX supplies sensory innervation to the mucosa of the middle ear. Along the branches of the tympanic plexus are paraganglionic cells, and the glomus tympanicum tumor arises from these cell groups associated with the tympanic plexus.

The chorda tympani arising from cranial nerve VII traverses the middle ear cavity but is not a source of innervation to the cavity.

The tympanic cavity derives its arterial supply from a number of vessels. Most are branches of the external carotid artery. The anterior tympanic artery arises from the internal maxillary artery; the inferior tympanic artery arises from the ascending pharyngeal artery. The stylomastoid artery arises from either the posterior auricular or the occipital artery and gives off the posterior tympanic artery. The superior tympanic and the petrosal artery arise from the middle meningeal artery, and the caroticotympanic branches arise from the internal carotid artery.

The veins roughly parallel the arteries and empty into the superior petrosal sinus and pterygoid plexus. The lymphatics begin as a network in the mucous membrane and end chiefly in the retropharyngeal lymph nodes.

Route of the Facial Nerve (Cranial Nerve VII)

The facial or seventh cranial nerve emerges from the brainstem as two roots, motor and sensory. The motor root is the larger one. It leaves the medulla oblongata at the inferior border of the pons, medial to the acoustic nerve. The smaller sensory root or nervus intermedius (of Wrisberg) contains efferent and visceral efferent fibers. It emerges from the medulla between the motor root of the facial nerve and the acoustic nerve.

As the motor root leaves the medulla, it pierces the pia mater and receives its sheath. The bundle then continues forward and laterally in the posterior fossa to the internal auditory meatus. The facial nerve enters the canal in conjunction with the nervus intermedius and acoustic nerve. As it spans the distance between the medulla and the porus acousticus, the motor root aligns itself in a groove on the superior surface of the cochlear division of the eighth nerve. This intracranial segment is 23 to 24 mm in length.

The internal auditory canal segment is 7 to 8 mm in length and is superior to the cochlear nerve, passing above the crista falciformis in the anterior upper portion of the canal. While within the canal, the motor root is separated from the acoustic bundle by the nervus intermedius, but the three nerve bundles are all surrounded by one sheath of arachnoid and dura and by continuations of the subarachnoid and subdural spaces. While still within the canal, the motor root and the nervus intermedius unite to form the combined nerve trunk.

The labyrinthine segment of the nerve measures 3 to 4 mm in length and passes forward and laterally within its own bony channel, the fallopian canal. This segment of the facial nerve canal travels anterolaterally, roughly perpendicular to the longitudinal axis of the petrous bone. The labyrinthine segment of the facial canal describes a subtle curve just superior to the cochlea and anterior to the semicircular canals. At the end of the labyrinthine segment is the geniculate ganglion. The ganglion represents only a small part of the nerve at this location. Only the cell bodies of the somatosensory and taste fibers are located in the ganglion. At approximately the position of the ganglion, the direction of the nerve reverses itself, executing a hairpin turn so that it runs posteriorly. This is the so-called anterior knee or first genu of the facial nerve. At this point the facial nerve is lying just above the base of the cochlea, that is, above and medial to the promontory. Here the nerve is very close to the cochleariform process.

The first genu of the facial nerve, in the limb distal to the geniculate ganglion, delineates the most anterior extent of the tympanic segment of the nerve. This tympanic segment is about 12 mm in length and passes posteriorly and laterally, in the long axis of the petrous bone and along the medial wall of the tympanic cavity. The nerve is contained within the tympanic segment of the facial nerve canal and courses just above the oval window and below the lateral semicircular canal. At the level of the sinus tympani, the nerve changes direction at the second genu. At this point the nerve assumes a vertical position, dropping down along the posterior wall of the tympanic cavity and passing through the anterior mastoid to exit at the base of the skull from the stylomastoid foramen. This mastoid segment is about 15 to 20 mm in length.[12]

There are three primary branches of the facial nerve: the greater superficial petrosal nerve, the nerve to the stapedius muscle, and the chorda tympani.

The greater superficial petrosal nerve leaves the facial nerve at the geniculate ganglion and exits the petrous bone and facial canal just anterior to the geniculate ganglion by way of the facial hiatus along the anterior aspect of the petrous pyramid. The greater superficial petrosal nerve is a mixed nerve, containing both parasympathetic fibers (from the nervus intermedius) and a few motor fibers. This nerve receives sympathetic fibers from the deep petrosal nerve, at which point it becomes the Vidian nerve.

The nerve to the stapedius muscle is a small twig given off from the facial nerve as it descends in the mastoid segment behind the pyramidal eminence.

The chorda tympani originates about 5 mm above the stylomastoid foramen. The chorda is composed mainly of sensory fibers but also contains a few parasympathetic fibers. As it leaves the trunk of the facial canal, it pursues a recurrent course upward and forward in the canaliculis chorda tympani (iter chordae posterius), a narrow canal in the posterior wall of the tympanic cavity. It enters the tympanic cavity close to the border of the tympanic membrane. It then crosses the cavity, running along the medial surface of the tympanic membrane at the junction of

Copyright © 2003, Mosby, Inc. All rights reserved.

its upper and middle thirds. It is covered by the mucous membrane lining of the tympanic cavity and passes lateral to the long process of the incus and then medial to the manubrium of the malleus above the tendon of the tensor tympani. It passes between the malleus and the incus. The chorda tympani leaves the tympanic cavity by way of a small canal in the medial petrotympanic fissure to pass to the base of the skull through a small foramen, the iter chordae anterius (anterior tympanic aperture). It eventually joins the lingual nerve to supply taste sensation to the anterior two thirds of the tongue.

Bony Dehiscences

It is customary to consider the facial canal a closed bony tube except where branches make their exit. Such is not invariably the case. Baxter reported dehiscence in more than half of over 500 temporal bones studied microscopically.[14] Dehiscences in the canal were most common in the tympanic portion near the oval window region and were occasionally present in the mastoid segment and near the region of the geniculate ganglion. The average dimension of these dehiscences was less than 1 mm. The radiologic demonstration of a substantial loss of bone in any region of the facial canal therefore should be considered abnormal. However, it should be remembered that the tympanic segment of the facial nerve canal is at about a 45° angle relative to the coronal plane. Because the angle of slice is oblique to the canal, partial volume effects can make the thin, bony cortex of the canal very difficult to visualize.

Anomalous Course in Petrous Bone

Although the course of the facial nerve through the temporal bone is one of the most constant anatomic relationships, anomalous courses do occur. Such a circumstance may be extremely treacherous for a surgeon, and everyone involved in the interpretation of temporal bone images must be alert to the possibility of such an anomaly.

An anomalous course of the mastoid portion is to be expected in the presence of atresia of the external acoustic canal (discussed later), but numerous such courses have been reported in the absence of any other significant developmental abnormality.

Most of the anomalous courses reported are involved in the part of the nerve peripheral to the geniculate ganglion. The interested reader is referred to the work of Basek, Schuknecht, Shambaugh, Dunkin et al., and Wright et al.[6, 12, 15–17]

The main trunk of the facial nerve in its tympanic portion may take an anomalous course along the medial wall of the tympanic cavity. If there is a delay in the formation of the bony covering of the tympanic segment, the nerve will appear to ''migrate'' inferiorly. The nerve can be slightly displaced and come to lie on the stapes. This migration tends to occur just as the crura of the stapes are forming and growing to meet the footplate of the stapes. The nerve can pass through this region and come to lie on the promontory of the cochlea. Rarely, the crura can actually attach to the nerve that passes directly across the oval window. In this instance the position of the nerve obviously limits the movement of the stapes, and a conductive hearing loss results.

The nerve may divide into two or more branches at any position along its course, and these branches may either parallel one another or diverge.

An anomalous course of the facial nerve within the tympanic cavity is difficult to diagnosis at imaging. The radiologist should confirm that the facial nerve is in the normal position in every case. The canal is usually seen as a small oval or ''notch'' just beneath the lateral semicircular canal. Lack of visualization of the notch should raise suspicion of an abnormal course of the facial nerve. The abnormally positioned nerve may be directly visible, passing along the promontory or even across the oval window. Preoperative identification of such an anomalous course can be very helpful to the surgeon and can help avoid an inadvertent iatrogenic facial nerve paralysis.

Inner Ear

Bony Labyrinth

The bony labyrinth consists of the vestibule, semicircular canals, and cochlea (Fig. 19-7).

Vestibule

The central portion of the cavity of the bony labyrinth is the vestibule. The vestibule is a relatively large ovoid perilymphatic space measuring approximately 4 mm in diameter. The vestibule is continuous anteriorly with the cochlea and posteriorly with the semicircular canals. There are cribrose areas, minute openings for the entrance of the nerve branches from the vestibular nerve on the medial wall and floor of the vestibule, where the vestibule abuts the lateral end of the internal acoustic canal. The vestibule has two other openings, the oval window (for the footplate of the stapes) and the vestibular aqueduct.

Semicircular Canals

The three semicircular canals are continuous with the vestibule. Each of the canals makes about two thirds of a circle and measures about 1 mm in cross-sectional diameter. Each canal is enlarged anteriorly by an ampulla. The nonampulated ends of the superior and posterior semicircular canals join to form the bony common crus.

A portion of the superior semicircular canal is closely related to a ridge (arcuate eminence) on the anterior surface of the petrous bone (the posterior delimitation of the middle cranial fossa). The lateral (horizontal) semicircular canal projects as a ridge on the medial wall of the attic.

The perilymphatic space of each semicircular canal opens into and communicates freely with the vestibule at both ends.

The superior and posterior semicircular canals are both arranged in a vertical orientation at approximately right angles to one another. The superior canal is directed anterolaterally at an angle of about 45° to the midsagittal plane, and the posterior canal is directed posterolaterally at a corresponding angle. It should be noted therefore that the angles of the vertical canals are oriented within both temporal bones so that the superior semicircular canal of one side has the same orientation as the posterior canal of the opposite side.

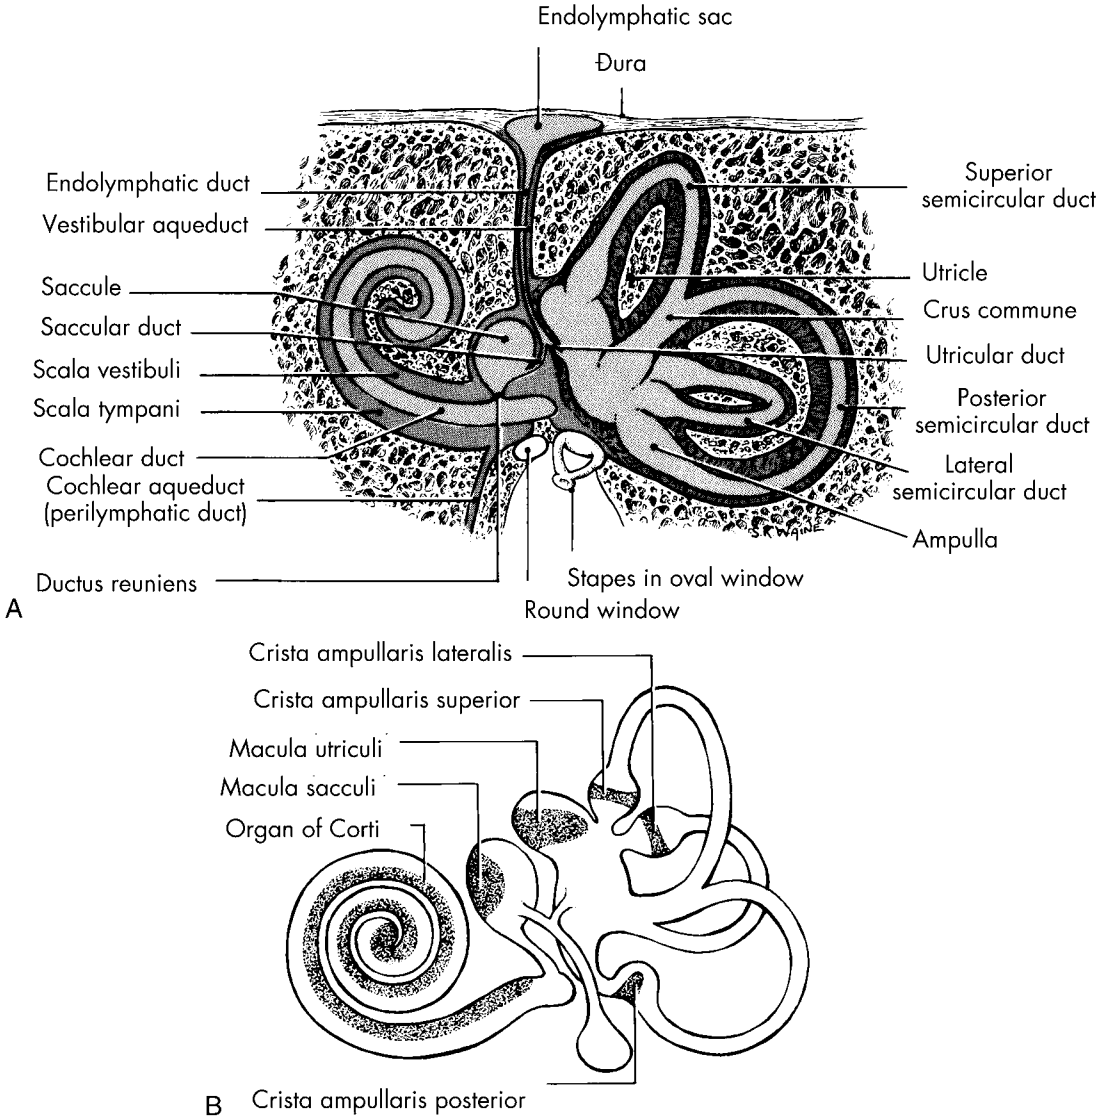

FIGURE 19-7 **A**, Inner ear, schematic drawing. The membranous labyrinth is enclosed within the bony labyrinth and separated from it by the perilymphatic space. The cochlear and vestibular portions of the membranous labyrinth are surrounded by perilymph. The vestibule and semicircular canals tend to be suspended from the walls of the bony labyrinth by myriad tiny arachnoid-like filaments. No such filaments exist around the cochlear duct. The membranous labyrinth encloses the endolymphatic space and is filled with endolymph. The endolymphatic sac and duct are in continuity with the endolymphatic space. The cochlear aqueduct communicates with the subarachnoid space and is in continuity with the perilymphatic space. The oval window abuts against the vestibule; the round window is located at the commencement of the basilar turn of the cochlea. The perilymphatic space is dark gray. **B**, Specialized sensory areas of the membranous labyrinth. Sensory cells mediating hearing are located in the organ of Corti within the cochlear duct. Sensory organs of the vestibular labyrinth are located in the maculae of the utricle and saccule and within the ampullae of the semicircular canals. The macula of the utricle mediates most of the sensations related to linear acceleration of the head; the ampullary cristae are sensitive to changes in angular acceleration of the head.

The lateral semicircular canal does not occupy a horizontal plane, and for this reason the older terminology (*horizontal*) has been discarded. The anterior limb of the lateral semicircular canal lies in the plane higher than the posterior limb, making an angle of about 30° with the horizonal. In the erect position therefore the neck would have to be flexed about 30° for the lateral semicircular canal to be ''horizontal.''

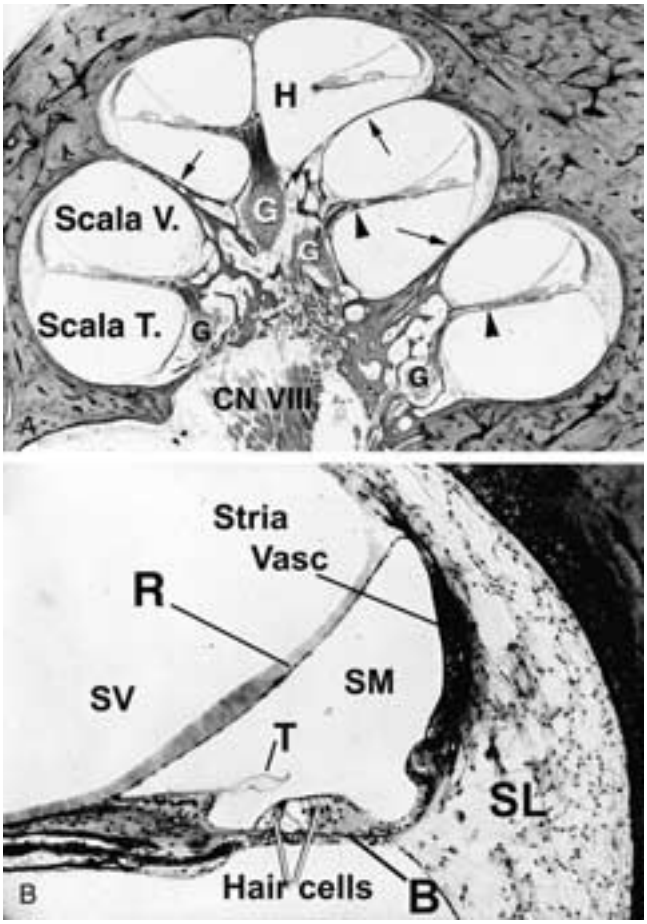
Cochlea

The perilymphatic cavity of the vestibule is also continuous with the cochlea anteriorly (Fig. 19-8 and see the figures in the next section). The cochlea is a conical structure, its base facing the internal auditory canal and its apex or cupola directed anteriorly, laterally, and slightly downward. The base measures around 9 mm, and its axis height is about 5 mm. The base is perforated by numerous apertures for the passage of the cochlear nerve. The cochlea consists of a bony canal wound around a conical central core called the modiolus. The canal winds through slightly more than 2½ turns. The thin osseous spiral lamina projects from the modiolus into the canal and partially divides it. The division of the canal is completed by the basilar membrane, stretching from the free border of the osseous spiral lamina to the outer wall of the bony cochlea. The two passages into which the cochlear canal is thus divided communicate with each other at the apex of the modiolus by a small opening, the helicotrema.

The modiolus is the conical central pillar of the cochlea. Its base is broad and appears at the lateral end of the internal acoustic canal, where it corresponds with the cochlear exit of the corresponding part of the eighth cranial nerve. It is perforated by numerous orifices for the transmission of the branches of the nerve.

The bony cochlear canal takes between 2½ and 2¾ turns around the modiolus. The first turn bulges toward the tympanic cavity, and this elevation on the medial wall of the tympanic cavity is known as the promontory. The bony cochlear canal is about 30 mm long and diminishes gradually in diameter from the base to the summit, where it ends in the cupola, which forms the apex of the cochlea. The cross-sectional diameter of the beginning of the canal is about 3 mm. The openings in or near the first portion of the cochlear canal include the round window, which is covered by the secondary tympanic membrane; the oval window (actually an opening of the vestibule), which is covered by the footplate of the stapes; and the cochlear canaliculus, which leads via a small canal to the subarachnoid space, opening on the inferior surface of the petrous portion of the temporal bone. The cochlear canaliculus, also known as the cochlear aqueduct or perilymphatic duct, allows at least theoretical equilibration between the perilymphatic space and the subarachnoid space; however, it is usually completely filled with arachnoid and fibrous tissue.

The bone separating one turn of the cochlea from the next is called the interscalar septum.



VIEW IMAGE

FIGURE 19-8 **A**, Photomicrograph of a normal cochlea. The eighth cranial nerve (*CN VIII*) can be seen entering the modiolus. The modiolus forms the core or axis in the center portion of the cochlea. The modiolus contains the cells of the spiral ganglion (*G*) seen in several turns in this photomicrograph. Note that much of the bulk of the upper modiolus is composed of nerve rather than bone. The spiral lamina (*arrowheads*) projects from the modiolus into the turns of the cochlea. This partially separates the lumen of the cochlea into the scala vestibuli (*Scala V.*) and scala tympani (*Scala T.*). The scala vestibuli and scala tympani communicate at the helicotrema (*H*). The interscalar septum (*arrows*) is seen at several levels. **B**, The basilar membrane (*B*) extends from the spiral lamina to the spiral ligament (*SL*). The hair cells are seen in the organ of Corti. Small projections from the hair cells are stimulated by the tectorial membrane (*T*). Reissner's membrane (*R*) closes the cochlear duct and separates the scala media (*SM*) from the scala vestibuli (*SV*). Stria vasculare (*Stria Vasc.*)

Membranous Labyrinth

The interconnecting spaces actually within the membranous labyrinth (see Fig. 19-7) constitute the endolymphatic cavity. The membranous labyrinth consists of the cochlear duct, the vestibular sense organs, the endolymphatic duct and sac, the round window membrane, and the vascular system.

Cochlear Duct

The cochlear duct is a spiral tube lying within the cochlea and attached to its outer wall. The cochlear duct is a blind pouch; it cleaves the perilymphatic space within the bony labyrinth, dividing it into two portions, the scala vestibuli and the scala tympani (see Fig. 19-8). The cochlear duct is triangular, its roof being formed by Reisner's membrane, its outer wall by the endosteum lining the bony canal, and its floor by the basilar membrane and the outer part of the

Copyright © 2003, Mosby, Inc. All rights reserved.

osseous spiral lamina. It contains the organ of Corti, which is the site of placement of the supporting and sensory (hair) cells that mediate hearing.

Vestibular Sense Organs

The sensory organs of the vestibular labyrinth are located in the maculae of both the utricle and saccule and within the ampullae of the semicircular canals. The epithelium consists of supporting cells and hair cells (sensory cells) covered by a gelatinous layer into which the cilia project.

Vestibular physiology is complex. The maculae are referred to as organs of static balance because the otoliths, under the influence of gravity (they have a specific gravity of 2.71), exert traction on the cilia of the hair cells in varying positions of the head. The macula of the utricle mediates most of the sensations that have to do with linear acceleration of the head. The ampullary crests located within the semicircular canals are called organs of kinetic balance because they are stimulated by the movement of or pressure changes in the endolymph caused by the angular acceleration of the head; this produces deviation of the cupulae.

The utricle resides within the elliptical recess of the vestibule. The sensory cells of the utricle lie within the macula. The membranous semicircular ducts all open into the utricle. From the anteromedial part of the utricle the ductus utriculosaccularis takes its origin and opens into the endolymphatic duct.

The saccule lies in the spherical recess near the opening of the scala vestibuli of the cochlea. The macula of the saccule is located along its anterior wall. The saccule communicates with the sinus of the endolymphatic duct by way of the saccular duct, and from the lower part of the saccule the ductus reuniens communicates with the basal end of the cochlear duct.

The membranous semicircular ducts are about one quarter of the diameter of the osseous semicircular canals. Each duct has an ampulla at one end that lies within the ampulla of the corresponding bony canal. The semicircular ducts open by five orifices into the utricle, the common crus being a single opening for the junction of the medial end of the superior and the upper end of the posterior semicircular ducts. A crestlike septum, the ampullary crest, crosses the base of each ampulla and is made up of sensory epithelium distributed on a mound of connective tissue and covered by a gelatinous cupula.

Endolymphatic Duct and Sac

The endolymphatic duct begins within the vestibule as a dilated portion, the endolymphatic sinus. It arises at the confluence of the utricular and saccular ducts. As it leaves the vestibule, it narrows into an isthmus and passes into the vestibular aqueduct, located near the crus common. As the aqueduct turns caudally to approach the dural opening of the vestibular aqueduct, the membranous duct (within the bony aqueduct) widens again into the flat endolymphatic sac. The intraosseous part of the sac fills most of the vestibular aqueduct. The remainder of the sac protrudes from the inferior aperture of the aqueduct and lies between the periosteum of the petrous bone and the dura mater. The sac is not one compartment but rather a complex system of connecting channels.

Round Window Membrane

The round window membrane (secondary tympanic membrane) measures about 3 mm in its horizontal axis and about 1.5 mm in its transverse axis. The round window membrane is of particular importance in acoustic energy transfer within the inner ear, where it performs as a yielding area of the bony labyrinth to permit movement of the perilymph in association with excursions of the stapedial footplate. Typically, movements of these two diaphragms should be 180° out of phase with one another.

Vascular System

The arterial blood supply to the membranous labyrinth originates within the cranial cavity and effectively is distinct from the vessels that supply the otic capsule and the tympanic cavity, although there are a few terminal branches that penetrate the endosteal layer. In a study of 100 human specimens, Mazzoni reported finding a consistent arterial loop in the region of the internal auditory canal.[18] This loop is either the main trunk or a branch of the anterior inferior cerebellar artery in 80% of cases, of the accessory anterior cerebellar artery in 17%, or a branch of the posterior inferior cerebellar artery in 3%. The loop was found inside the internal auditory canal in 40%, at the porus in 37%, and within the cerebellopontine angle cistern in 33% of cases.

The anterior inferior cerebellar artery (AICA) arterial loop gives rise to the internal auditory artery (labyrinthine artery) and also frequently to the subarcuate artery. The AICA then takes a recurrent course to the cerebellum. The internal auditory artery distributes to the dura and nerves in the internal auditory canal, to adjacent bone of the canal, and to the medial aspect of the inner ear before dividing into the common cochlear artery.[18] The further ramifications of these arteries to the membranous labyrinth are discussed by Hawkins and are further elaborated on by Schuknecht.[12, 19]

The main venous channels of the cochlea are the posterior and anterior spiral veins. These join together near the base of the cochlea to form the common modiolar vein. The common modiolar vein is joined by the vestibulocochlear vein to become the vein of the cochlear aqueduct. This main channel enters a bony canal near (but not within) the cochlear aqueduct to empty into the inferior petrosal sinus.

The semicircular canals are drained by vessels that pass toward the utricular end to form the vein of the vestibular aqueduct, which accompanies the endolymphatic duct and drains into the lateral venous sinus.

Bast and Anson describe an internal auditory vein that traverses the internal auditory canal and drains into the inferior petrosal sinus, but this is an inconstant vessel.[3]

Perilymphatic Spaces and Fluid Systems

The perilymphatic space (see Fig. 19-7) of each semicircular canal is continuous at both ends with the perilymphatic space of the vestibule, and this space is in turn continuous widely with that of the scala vestibuli. The scala vestibuli is continuous with the scala tympani at the helicotrema. All the perilymphatic spaces therefore open widely into each other.

The total volume of fluid contained within the develop-

Copyright © 2003, Mosby, Inc. All rights reserved.

mentally mature periotic space is estimated to be approximately 0.2 ml or about three drops. Without those three drops of fluid, the transmission of sound waves from the oval window to Reissner's membrane in the cochlea could not be mediated.

There are several actual or potential dehiscences in the compact bone of the petrous portion of the temporal bone that could theoretically permit abnormal communication between the perilymphatic space and the bordering structures.[10] These include (1) the oval window, normally sealed off from the middle ear cavity by the footplate of the stapes and its annular ligament; (2) the round window, normally sealed off from the middle ear by the secondary tympanic membrane; (3) the fissula ante fenestram and the fossula postfenestram, two small extensions of the perilymphatic space extending from the vestibule toward the middle ear cavity that are usually obliterated by connective tissue; and (4) the vestibular aqueduct, a channel that extends through the otic capsule from the vestibule to the posterior cranial fossa and transmits the endolymphatic duct and accompanying vein. The duct, vein, and connective tissue surrounding them so fill the aqueduct that there is no perilymphatic space and therefore no actual communication between the perilymphatic space of the vestibule and the epidural space. The fifth actual or potential dehiscence is the cochlear aqueduct (perilymphatic duct, cochlear canaliculus), a normally minute canal that opens on the inferior surface of the petrous part of the temporal bone and permits communication between the subarachnoid space and the scala tympani. Occasionally the cochlear aqueduct is very patulous, although filled with arachnoid and fibrous tissue, and this provides at least a theoretical possibility of free communication of the perilymphatic space with the subarachnoid space. Whether this is physiologically important in the transport of potentially noxious substances to the inner ear from the violated subarachnoid space is unproved.

HOW THE EAR AMPLIFIES SOUND

Once the inner ear becomes sequestered within the base of the skull, it becomes necessary in the evolutionary sense to reestablish continuity with the external environment so as to provide a suitable apparatus for the reception of sound. Evolution elegantly fashioned a solution based on the simplest of mechanical and hydraulic principles. The ossicular chain acts as a simple lever mechanism attached to the large-area diaphragm (tympanic membrane) on one side and the small-area diaphragm (stapes footplate) on the fluid side.

Sound waves are amplified by three different mechanisms by the time the vibrations in the air of the external acoustic canal are changed to fluid pulsations of the perilymph within the membranous labyrinth.

The first mechanism is the ''organ pipe'' resonance of the external canal. The resonant frequency of the column of air enclosed within the external acoustic canal accounts for approximate doubling of the pressure at the tympanic membrane compared to that at the entrance to the canal for frequencies between 2000 and 5400 Hz.

Secondly, the area of the tympanic membrane varies between 15 and 30 times the area of the oval window. This concentration of force at the stapes footplate amplifies the incoming vibrations of sound approximately 15 to 30 times.

Finally, the lever mechanism of the ossicular chain reduces the amplitude of the excursion of the bone at the footplate of the stapes in comparison to the long handle of the malleus and thereby increases the force by a factor of 2 to 3.

The sound waves therefore may be amplified by a factor of up to 180 by the time they encounter the perilymph.[20]

SECTION TWO

SECTIONAL ANATOMY

Hugh D. Curtin and Pina Sanelli

The radiologist is presented with the anatomy of the temporal bone as planar sectional images.[1–7] The axial and coronal planes are currently considered standard in modern imaging only because these planes were most conveniently achieved by the typical CT scanner of the 1980s and 1990s. The patient was positioned routinely on the back, with the head comfortably placed in a neutral position for axial images. For coronal images, the patient was placed in either the supine or prone position, and the neck was extended as far as possible. Although oblique planes were occasionally attempted, patient positioning was uncomfortable and these planes were never widely accepted. MR imaging is capable of oblique planar imaging but lacks the ability to define the fine cortical bony anatomy of the temporal bone.

Prior to the advent of CT, multiplanar imaging using pluridirectional tomography was routine. Many different obliquities were used to generate a perfect cross-sectional image through a particular part of the temporal bone anatomy. Indeed, coronal and sagittal images were routine. Axial images were more difficult to achieve because of the awkward patient position needed for the basal view. Oblique planes carried names such as Poschl, Guillen, Stenvers, and so on, named after the people who described them. Each plane was designed to optimize visualization of a certain structure. The design of the planes was based on the principle that the optimal plane for visualization of a plate of bone or a relatively linear structure is in a plane perpendicular to the structure. Subtle angles were measured and precise obliquities were generated.

Now, with the introduction of multidetector spiral CT scanners, an entire volume of the temporal bone is examined with one pass of the scanner in one plane. The volume is organized based on the *isotropic voxel* and spatial resolution is the same in any plane, be it the plane of acquisition or a reconstructed plane. The data set can be sectioned in virtually any plane. The plane of the reformatted image is not governed by ease of patient positioning, but rather by the optimal plane for visualizing a structure.

As the plane of the final image is not dependent on the original scan angle, the scan can be performed while avoiding direct irradiation of the lens of the eye (Fig. 19-9). The ideal orientation for even the axial plane can then be generated as a reformatted image. Most of the images in this section are reformatted images rather than direct scans.

The following images detail the anatomy of the temporal bone in various planes of section. Images are provided in the routine axial and coronal planes with several gross anatomic cross sections for comparison (see Figs. 19-10 to 19-14). Other planes are shown for imaging of particular anatomic structures (see Figs. 19-15 to 19-17).

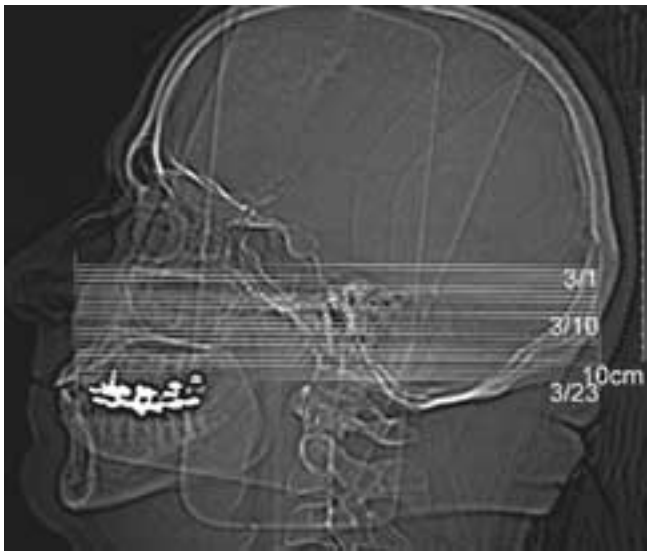

FIGURE 19-9 Original plane of sections. The scan angle is chosen to cover the temporal bone but to avoid the eye, in particular the lens of the eye.

Scout

FIGURE 19-10 **A** to **L**, Axial images taken approximately along the anthropomorphic baseline. These are approximately parallel to the original scan angle. However, the scans were prescribed from a sagittal plane preliminary view, reformatted along the axis of the cochlea (*see inset*). These scans correspond approximately to the gross section shown in Figure 3. At level **D**, the labyrinthine segment of the facial nerve canal courses from the internal auditory canal toward the geniculate turn of the facial nerve. The tympanic segment then passes posteriorly along the medial wall of the middle ear. At level **E** the tympanic segment of the facial nerve passes beneath the horizontal semicircular canal. The ''ice cream cone'' configuration of the malleus head (the ice cream) and the incus (the cone) is appreciated at this level.

HIGH-RESOLUTION T2-WEIGHTED IMAGING
HIGH-RESOLUTION T1-WEIGHTED CONTRAST IMAGES
MAGNETIC RESONANCE ANGIOGRAPHY
CONCLUSION

Temporal bone imaging is extremely challenging, as the normal anatomy includes many small but clinically important structures, and a significant abnormality in this area may be less than 1 mm in size. The wide range of tissues existing in the area must be evaluated simultaneously, making it impossible to develop a single optimal imaging technique for studying all potential pathology. One must use both computed tomography (CT) and magnetic resonance (MR) imaging techniques of the highest possible resolution to precisely characterize the bone, air spaces, and the wide variety of soft tissues present in the temporal bone region. Often it is necessary to use both CT and MR imaging for satisfactory tissue characterization and identification of pathology or confident exclusion of abnormalities. This chapter reviews CT and MR imaging techniques appropriate for evaluation of the temporal bone. A more complete atlas using multiplanar CT is provided in Chapter 19.

CT excels in the evaluation of disorders that primarily affect air spaces or cortical bone.[1–8] Although the wide differences in the density of the temporal bone structures produce excellent inherent image contrast on CT, soft-tissue characterization is much more limited than with MR imaging. Thus, with CT, the individual cranial nerves cannot be seen without the use of intrathecal cisternography, a technique no longer commonly used and currently replaced by high-resolution MR imaging. In contrast, MR imaging provides poor information about the air spaces and cortical bone but excellent soft-tissue contrast resolution. In addition, MR is more sensitive to the effects of gadolinium as a contrast agent than is CT to iodinated contrast agents. In fact, CT contrast enhancement may be difficult to visualize within the temporal bone itself due to the high density of the bone. For example, enhancement of the vestibule in inflammatory pathology is quite conspicuous on MR (since the surrounding bone is a signal void), while the same enhancement is impossible to recognize using CT. Although one may not be able to visualize the architecture of the normal bone and air spaces, MR imaging can still provide useful information about these structures in diseased states, as there is signal due to fluid or a mass where normally there should be a signal void from either cortical bone or air.

These techniques can be complementary. For example, in the case of paragangliomas, CT can best demonstrate pathologic bone destruction, while MR more clearly displays vascular invasion or intracranial extension. Fast CT imaging can be used to create postprocessed angiographic studies, but the dense bone often presents difficulties in the reconstructions. MR imaging can also be used to generate excellent angiographic information; however, routine catheter angiography remains important for vascular imaging and is still the gold standard for analyzing the most challenging vascular pathology. Catheter angiography is also used to direct interventional procedures. Catheter angiography will not be discussed in this chapter.

COMPUTED TOMOGRAPHY: TECHNICAL CONSIDERATIONS

If the goal of a temporal bone CT study is to focus on the otic capsule, cortical plates, ossicles, and the air spaces alone, such as when studying a temporal bone fracture, then high-resolution bone algorithm techniques may be adequate.[1–8] However, if it is also important to evaluate the soft tissues, as in the case of a patient with cancer of the external auditory canal (EAC), then it may be necessary to use intravenous contrast and techniques similar to those used for a brain or soft-tissue neck study. The main disadvantages of CT are poor soft-tissue definition within the bony labyrinth and internal auditory canal (IAC) and radiation exposure for the patient. Although in the past it was essential to position the patient for axial and/or coronal images (Figs. 20-1 to

20-3), newer high-resolution multidetector spiral imaging systems can generate nearly isotropic voxels for multiplanar reconstructions, making the need for multiple series with direct imaging in several planes unnecessary. Postprocessing software has also improved, allowing multiplanar cross sections (Figs. 20-4 to 20-6), as well as transparent and surface volume image presentations (Figs. 20-7 to 20-12). A nearly perfect ''solid model'' of the temporal bone can be created from routine clinical CT data acquisitions.

Typically, a high-resolution matrix should be used (512 × 512), with thin sections (0.6 to 1.5 mm) and a field of view of 15 to 20 cm. CT images can be rapidly acquired, either sequentially or using a spiral technique. The exact technique, including collimation and reconstruction algorithms of spiral imaging, depends on the specifications of a particular piece of equipment. The faster the data acquisition, the less likely it is that the examination will be degraded by motion artifact. A low-mA (70 mA) technique is adequate for most of the bony structures, but higher mA (250 to 400 mA) techniques, thicker slices (3 to 5 mm), and contrast enhancement are necessary for the evaluation of the brain and other soft tissues.

CT images are usually acquired or displayed in axial and coronal planes. For axial imaging, sections are made in a plane rotated 30° superior to the anthropologic base line (the line intersecting the inferior orbital rim and the EAC). Scans produced in this plane display the temporal bone structures to good advantage.[3] This plane allows separation of the individual components of the temporal bone so that they are better visualized in their entirety, with less overlap and fewer partial volume imaging artifacts.[2] Direct coronal images are usually obtained at an angle of approximately 120° from the anthropologic baseline, while reconstruction coronal images are usually oriented 90° from the anthropologic baseline. Sagittal images can be very helpful in selected situations, and postprocessing can create multiple oblique or curved projections. For example, a plane rotated approximately 45° between the coronal and sagittal planes approximates Stenver's view and produces an image section plane parallel to the long axis of the temporal bone (see Chapter 19). Curved sections parallel to structures of interest (such as segments of the facial nerve canal) can be individually created, as can three-dimensional (3D) surface

reconstructions, allowing physical models to be created from the imaging data (Figs. 20-7 to 20-12).

MR IMAGING TECHNIQUES

The MR images in this chapter were obtained with a 1.5 Tesla General Electric Signa LX CDI Horizon imaging system. MR imaging has become the primary imaging modality for evaluation of the nonosseous components of the temporal bone region, including the major blood vessels, fluid spaces (cerebrospinal fluid, endolymph, perilymph), nerves, muscle, cartilage, brain, salivary glands, and fat (Figs. 20-13 to 20-22).[9–36] The spatial resolution currently available with MR has progressed to a point where it is comparable to and can even exceed that of CT.[12, 21]

As spatial resolution increases, the images become noisier as a result of an inherently decreased signal-to-noise ratio within any given voxel. This produces poorer-quality images when larger matrices are used, despite better spatial resolution. There are a number of strategies to deal with the potential low signal-to-noise ratio and poor image quality. Three-dimensional Fourier transform imaging (3DFT) uses radio frequency (RF) signal from an entire imaging volume during the entire acquisition rather than a single slice, thus increasing the signal-to-noise ratio. Therefore, very thin sections can be obtained for high-resolution 3DFT T1- and T2-weighted images.[9] Both gradient and spin-echo 3DFT techniques are possible.[10, 20, 22, 24, 28] If short TE times are available and the sequences are optimized, the quality of the examination using a gradient echo technique can rival or surpass spin-echo alternatives. For T1 weighting, spoiled gradient echo imaging with short TR (50 ms) and TE (4 ms), and with flip angles of 30°, generate images similar to routine spin-echo images but can also demonstrate the vessels to advantage.[36] Caution must be exercised, as high signal of vessels may be mistaken for enhancement in a tumor. For this reason, some radiologists prefer standard high-resolution, thin-slice postcontrast 2D spin-echo sequences for evaluation of the IAC. Steady-state T2-weighted gradient echo images using constructive interference techniques also have excellent quality and are not marred by increased magnetic susceptibility artifacts because of their short TE times.[11, 12, 20, 22, 29] One can also utilize a T2-weighted 3DFT gradient echo technique called SIMCAST (segment-interleaved motion-compensated acquisition in a steady state).[29] Two-dimensional Fourier transform and 3DFT T2-weighted spin-echo imaging techniques are also possible.[28] The resulting images using the gradient and spin-echo 3DFT techniques are comparable and have similar acquisition times.

The signal-to-noise ratio can be improved by using dedicated phased-array surface coils specifically designed for temporal bone imaging.[30, 31] Such phased array coils are more effective than those obtained by simply combining a series of routine coils to a single input. Each phased-array coil is composed of two or more separate but overlapping

coil loops. Phased-array coils also allow shorter imaging times. The disadvantage of using these coils is that the images are not homogeneous in signal intensity, and the coils are more cumbersome for the technologist to position. Using surface coils to study the superficial structures can increase the signal-to-noise ratio approximately three to five times compared with that of a routine head coil.

Gradient echo imaging is more sensitive to a number of factors, including T2* signal loss from magnetic susceptibility artifacts, and magnetic susceptibility between water and air can result in a distortion of MR images somewhat similar to chemical shift artifact. These local magnetic field distortions are exaggerated with high-resolution imaging, narrow bandwidth, and high magnetic field strength. Magnetic susceptibility artifacts may be seen as regions of high and low signal in locations near the oval and round windows not corresponding to anatomic structures (see Fig. 20-13D).[20] Gradient echo techniques have been developed that use short TE times to specifically suppress these artifacts since they are more pronounced with increasing TE. Though spin-echo images are not immune to these artifacts, they are less sensitive. Short TE times increase the signal-to-noise ratio by diminishing the effects of T2* decay, and short TE times limit the effects of magnetic susceptibility artifacts that occur at the air-water interfaces of the oval and round windows.[22] A short TE time allows fat and water to be in phase, thus diminishing the artifacts associated with intravoxel fat-water subtraction seen with gradient-echo high-resolution imaging.[36] The ideal TE time varies with field strength.

Contrast-enhanced studies are of value in many situations.[32–36] An enhanced study can be acquired as 2DFT T1-weighted axial or coronal series of the whole brain. A 3DFT T1-weighted axial MR series can also be acquired.

FOUR BASIC MR IMAGING PROTOCOLS

Four basic MR imaging protocol techniques are used to address specific goals: whole brain/head imaging, high-resolution fluid space imaging, high-resolution T1-weighted, contrast-enhanced imaging, and MR angiography (MRA) techniques (Table 20-1). The actual sequences used vary from institution to institution and with the specific MR scanner utilized.

Some radiologists feel that the demonstration of high signal in blood vessels on T1-weighted images is helpful. Others feel that signal of the small vessels in the IAC can be confusing when looking for subtle enhancement of a small eighth nerve tumor, and they therefore prefer spin echo T1-weighted images with contrast enhancement for evaluation of sensorineural hearing loss. The lack of any high signal within the canal on this sequence is a reliable

indicator that no eighth nerve tumor is present. A thin section 2DFT spin-echo T1-weighted sequence is obtained in the axial plane after intravenous gadolinium administration. Typical parameters include TR of 450, TE of 15, three acquisitions, a field of view of 170 mm, and a matrix of 192 × 256. Some radiologists add fat suppression to eliminate potentially confusing high signal from the fat in the petrous apex.

ROUTINE BRAIN SURVEY

Routine head imaging is important to evaluate brain or other soft-tissue pathology. For example, a patient who presents with symptoms of dizziness could have pathology that results from brainstem demyelination or a tumor. For this reason, images of the whole brain are routinely obtained. Acquisition of a noncontrast T1-weighted sequence is of value to help characterize high-signal regions on contrast studies, since without a noncontrast examination, it may be difficult to differentiate fat or subacute hemorrhage. T1-weighted, contrast-enhanced studies are routinely acquired. In general, lower-resolution 2DFT T1-weighted images are acquired to evaluate the brain and adjacent soft-tissue structures, while fat saturation and contrast enhancement may be of value if the suspected pathology involves the fat spaces.

Low- to high-resolution axial (256 × 256 matrix, 4 to 5 mm thick) fluid-attenuated inversion recovery (FLAIR) and T2-weighted fast spin-echo (FSE) images are also used to evaluate the brain. The FLAIR images are particularly sensitive to brain pathology such as demyelination or infarcts, and they are also helpful in differentiating hemorrhage from fat.

HIGH-RESOLUTION T2-WEIGHTED IMAGING

Fluid-sensitive high-resolution images are noncontrast enhanced and demonstrate the CSF and endolymphatic spaces as high signal intensity regions. The cisternal cranial nerves can be visualized without contrast using this technique since the nerves are surrounded by the higher signal intensity fluid. Fluid in the otic capsule structures is best visualized utilizing this technique, making it possible to evaluate cochlear or vestibular pathology. This technique has been used as a screening technique to rule out vestibular schwannomas.[36]

T2-weighted high-resolution images can be acquired

with short TR, low flip angle gradient-echo 3DFT imaging. This is achieved by preserving rather than spoiling transverse magnetization using an appropriate selection of rephasing gradients, a short TR (20 to 30 ms) and a moderate flip angle (30° to 50°). Such images are referred to as steady-state or steady-state-free-precession images. Stationary fluid with long T2 relaxation time yields high signal intensity similar to that seen on standard T2-weighted spin-echo images. However, for fluid in motion (such as CSF in the cerebellopontine angle), the transverse magnetization is spoiled due to the motion, and the fluid gives very low signal intensity. Other differences between steady-state

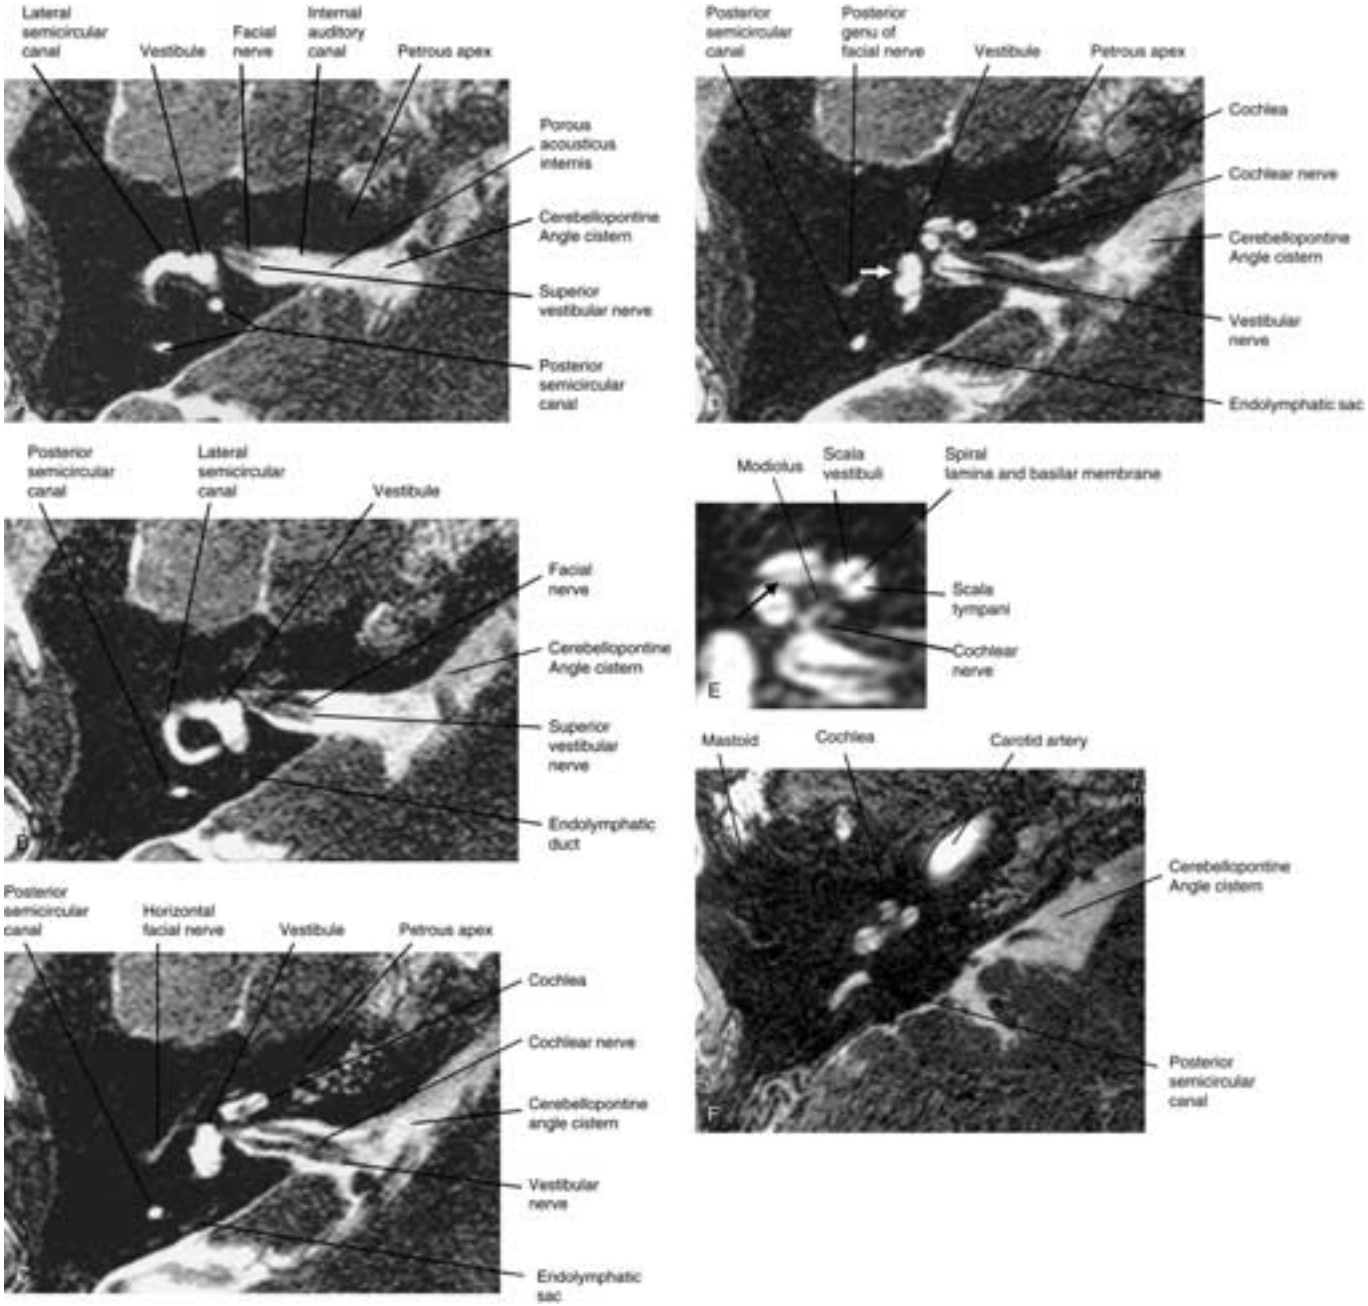

FIGURE 20-13 **A** to **F**, Axial MR imaging, IAC level. Each axial image is a gradient echo steady-state SIMCAST 0.7 mm thick, 1024 × 1024 matrix axial section of the right temporal bone. The images appear to be T2-weighted, although the origin of the contrast is more complicated. The CSF and other fluid spaces demonstrate high signal intensity. The brain is intermediate in signal intensity, and the bone and pneumatized air spaces are signal voids. The IAC contains the seventh and eighth nerves. They are seen as thin, linear low signal intensity structures in the canal. The cochlea, vestibule, and semicircular canals are well seen. This section is not made 30° from the anthropologic baseline, so the complete lateral semicircular canal is not seen. The endolymphatic sac is seen posterior and medial to the posterior semicircular canal. In **D** the apparent notch (*arrow*) in the margin of the vestibule is susceptibility artifact. **E** is a magnified view of the cochlea at approximately the same level as **D**. Note the interscalar septum (*arrow*). Compare to the image provided by CT in Figures 19-10 and 19-11.

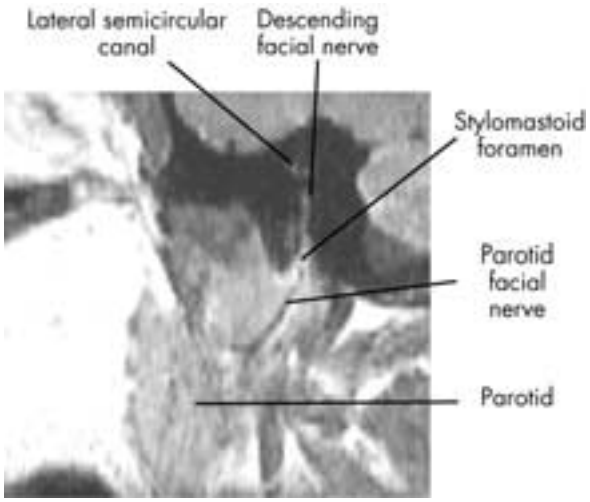
and standard T2-weighted spin-echo images include high signal for fatty tissue (with a short T1 relaxation time) and low signal intensity for all other tissues (gray matter, white matter, and muscle). Typical parameters of an unspoiled 3DFT axial series include 0.8 mm thick sections, a 512 × 288 matrix, 60 slices, TR of 17, TE of 4, flip angle of 30, NEX 1.[36] Postprocessing of the image data can create any specific projection or surface desired.

A common spin-echo alternative to this type of T2-weighted sequence is a 3DFT FSE technique that utilizes a TR of 5000, TE of 100, echo train of 16, matrix of 512 × 384, and a small field of view. Fat and spatial saturation pulses may be needed to suppress chemical shift and blood flow artifacts.



VIEW IMAGE

FIGURE 20-16 Sagittal MR imaging, descending facial nerve level. At the posterior genu, the facial nerve turns inferiorly, exiting the temporal bone through the stylomastoid foramen.

HIGH-RESOLUTION T1-WEIGHTED CONTRAST IMAGES

A high-resolution, contrast-enhanced T1-weighted technique similar to the T2-weighted studies can be acquired using a 3DFT technique to evaluate the temporal bone, but in this case the fluid spaces have low signal intensity and the nerves have higher signal intensity. This technique is also used to generate MRA images. Intravenous contrast enhancement is commonly used in conjunction with this type of technique. This sequence is ideal for identification of subtle changes, like those seen with vestibulitis or small vestibular tumors. T1-weighted gradient-echo images can be acquired by using a moderate TR (30 to 50 ms) and flip angle (30° to 50°) and by spoiling (destroying residual transverse magnetization). Spoiling is achieved by using spoiler gradients or, more efficiently, by utilizing RF spoiling (i.e., by randomizing the RF excitation pulse phase). Spoiling is needed to eliminate T2 contrast components from the acquired signal, thus yielding T1-weighted images that can be used to increase the visualization of the gray-white matter interfaces and create other section planes using postprocessing of the volume data sets. Routine spin-echo T1-weighted images can be utilized, but the resolution is significantly lower.

As vessels can be bright with 3D gradient echo sequences, some radiologists prefer the standard 2DFT FSE sequences. Although the images are slightly thicker, the in-plane resolution is high and the images depict the anatomy very well. Flow-related signal is less likely to be confused with subtle enhancement.

MAGNETIC RESONANCE ANGIOGRAPHY

Finally, a dedicated MRA acquisition may be of value in specific instances (Figs. 20-21 and 20-22). Different

techniques must be utilized for visualization of arterial versus venous anatomy. For arterial studies, 3DFT sequences generate the best detail and are usually not acquired with contrast enhancement. The 3DFT T1-weighted high-resolution technique previously described can be used as an excellent MRA technique as well. MRA sequences are designed to minimize stationary tissue signal by using a TE for which fat and water are out of phase or by using magnetization transfer. Flow compensation decreases signal from the moving CSF and thereby increases the contrast-to-noise-ratio between the blood vessels and the CSF in MRA; therefore, the soft-tissue detail may be poor. Although current MRA can provide high-quality images, they cannot substitute for traditional catheter angiography in many cases.

Venous anatomy must be studied using a different technique since the venous structures are much more sensitive to saturation because of slower flow rates. For venous anatomy, a technique employing a series of contiguous 2DFT coronal or axial images without saturation pulses is commonly used. Both the arteries and veins are seen, but there is usually little confusion. Common parameters include a TR of 26, a TE of 7, a flip angle of 60°, a matrix 256 × 192, no spatial saturation pulses, and a field of view of 24 cm. If saturation pulses are used, there is potential for demonstration of an artificial ''thrombosis,'' caused by low signal intensity resulting from saturation of inflowing spins. This is a *time of flight* technique, so coronal and axial images have different advantages to avoid saturation effects. Postprocessing of these volume data sets can be used to create detailed 3D projections in different planes and perspectives.

CONCLUSION

Temporal bone imaging remains at the forefront of the development of high-resolution imaging techniques of the body. The improved detection and understanding of temporal bone pathology provided by modern imaging methods allows for a very precise assessment of most pathologic entities. A thorough understanding of the anatomy is very important in correctly assessing pathology. The myriad formats in which the same anatomic region is presented continue to challenge radiologists.

Temporal Bone: Congenital Anomalies

Laura V. Romo, Jan W. Casselman, and Caroline D. Robson

INTRODUCTION
ANOMALIES OF THE OUTER EAR
- Associated Middle Ear and Ossicular Abnormalities
- Other Associated Abnormalities
- Surgical Considerations

ANOMALIES OF THE MIDDLE EAR
ANOMALIES OF THE INNER EAR
- Imaging Techniques
- Membranous and Bony Labyrinthine Anomalies
  - Semicircular Canals
  - Vestibule/Utriculosaccular Structures
  - Cochlea
- Other Anomalies
  - Internal Auditory Canal and the Vestibulocochlear and Facial Nerves
  - Vestibular Aqueduct

VASCULAR ANOMALIES
- Internal Carotid and Stapedial Arteries
  - Partial Absence and Aberrant (Lateral) Course
  - Agenesis
- Jugular Vein
  - High Jugular Bulb
    - *Protruding/Dehiscent Jugular Bulb*
    - *Jugular Diverticulum*
    - *Agenesis and Stenosis*

MALFORMATIONS OF THE PETROUS BONE ASSOCIATED WITH MENINGITIS
- Perilabyrinthine Fistulas
  - Dehiscence of the Tegmen Tympani
  - Hyrtl's Fissure
  - Fissula Antefenestram
  - Giant Apical Air Cell and Apical Meningocele
  - Petromastoid Canal
  - Widened Labyrinthine Segment of the Facial Nerve Canal
- Translabyrinthine Fistulas

CONGENITAL SYNDROMES INVOLVING THE EAR

INTRODUCTION

The temporal bone develops from two separate precursors. The pars branchialis radiates from the first and second branchial arches, the first branchial groove, and the adjacent mesenchyme. The pars otica develops from the auditory vesicle and the adjacent mesenchyme. The development of the external ear and the middle ear is therefore independent of the development of the inner ear. One portion of the ear may be normal, while another portion may be grossly malformed.[1–4] Because the development of the external and middle ears is closely linked, significant malformations of the external auditory canal are usually accompanied by middle ear deformities and vice versa. Inner ear anomalies usually occur independently. However, compared to the normal population, inner ear anomalies do occur more frequently in patients with anomalies of the other compartments.

Mesenchyme is involved in the development of all portions of the ear, so there are certain situations in which combined malformations characteristically occur. The toxic embryopathy subsequent to maternal ingestion of thalidomide is an example of such a situation, and some of the otocranio-facial dysplasias show similar combined malformations (Table 21-1).

Table 21-1
SYNDROMES WITH CONGENITAL ABNORMALITIES OF THE EAR

Syndrome	Ear Abnormalities (Outer)	Ear Abnormalities (Middle)	Ear Abnormalities (Inner)	Major Associated Anomalies
Achondroplasia (chondrodystrophia fetalis) **(Otoskeletal or AD)**	None	Ossicular fusion; dense, thick trabeculae without islands of cartilage in the enchondral bone and periosteal bone	Deformed cochlea; thickened intercochlear partitions	Dwarfism
Alagille syndrome (arteriohepatic dysplasia) **(AD)**	Large ears; incompletely folded helices	Bulky incus/stapes; immature interossicular joints	Dysplastic cochlea; partial or total absence of posterior and anterior SCCs; absence or stenosis of ICA	Intrahepatic cholestasis secondary to decreased intrahepatic ducts; peripheral pulmonary artery stenosis
Apert's syndrome (acrocephalosyndactyly) **(Otocraniofacial)**	None	Fixation of the stapes footplate	Patent cochlear aqueduct; enlarged IAC; unusually large subarcuate fossa that connects to middle fossa dura	Craniosynotosis, midface hypoplasia; exophthalmos; high palatal arch; syndactyly of hands and feet; hypertelorism; antimongoloid slant; crowded teeth
Branchio-otorenal dysplasia (Melnick-Fraser syndrome) **(Otocraniofacial or AD)**	Preauricular pits or fistulas; small ears; low-set ears; cup-shaped anteverted pinnae	Shortened manubrium of malleus or long process of incus; bulky malleus or incus; absent stapes; fixation of malleus or incus to attic; dysplasia or fixation of stapedial footplate; lateral ossicular displacement; small middle ear cavity; absent oval window or stapedial tendon; large or deep OW; hypoplastic facial nerve with dehiscent canal	Dilated vestibule; small SCCs; saccular LSCC; cochlear hypoplasia; enlarged endolymphatic duct (ELD)	Cervical fistulas or cysts; renal abnormalities; long, narrow facies; stenosis/atresia of nasolacrimal duct; retrognathia
CHARGE association (coloboma, heart anomaly, choanal atresia; retardation; and genital and ear anomalies) **(Unknown Mode of Inheritance)**	Small ears; cup-shaped lop ears; low-set short and wide, cup-shaped ears with triangular concha; small or absent ear lobes; ''snipped-off'' helical folds	Absent stapes suprastructure; foreshortened incus with missing long process; misshapen stapes footplate; absent stapedial tendon and pyramidal process, absent OW and RW	Mondini dysplasia of pars inferior; absent pars superior; short cochlea; hypoplasia of vestibular sense organs and nerves	Colobomas of eye; congenital heart anomalies (tetralogy of fallot, ASD, VSD, PDA); choanal atresia; short stature secondary to growth retardation developmental delay; mental retardation; CNS anomalies; genital hypoplasia
Chromosome 18 deletion syndrome **(Chromosomal)**	Low-set auricles, stenosis or atresia of EAC	Ossicular abnormalities	None	Hypertelorism; hypoplasia of midface; epicanthic folds; carp-shaped mouth; foot anomalies; mental retardation; congenital heart disease
Cleidocranial dyostosis **(Otocervical and AD)**	Atresia/narrowed EAC; small pinna	Marked sclerosis of mastoid; small ossicles; absent manubrium and long process of incus; fixation of stapes footplate; small tympanic cavity	Marked sclerosis of petrous bone	Large brachycephalic head; large fontanelles with wide sutures; partial or total aplasia of clavicles; spinal abnormalities; and small, poorly developed facial bones
Craniometaplyseal dysplasia (Pyle's syndrome) **(Otoskeletal and AD or AR)**	Sclerosis of canal	Enlargement of chorda tympani nerve; osseous proliferation within tympanic cavity; encasement of malleus in bone; deformed incus fixed by bone to promontory; stapes head in OW filled with bone; constriction of facial canal; obliteration of the mastoids	Constriction/sclerosis of IAC/meatus	Flask-shaped enlargement of the metaphysis of the long bones; overgrowth of the craniofacial skeleton; obliteration of the sinuses

Table 21-1
SYNDROMES WITH CONGENITAL ABNORMALITIES OF THE EAR *Continued*

Syndrome	Ear Abnormalities (Outer)	Ear Abnormalities (Middle)	Ear Abnormalities (Inner)	Major Associated Anomalies
Crouzon's disease (craniofacial dysostosis) **(Otocraniofacial or AD)**	Stenosis or atresia of EAC; rotated ears; low-set ears; microtia	Absent TM; distortion/narrowing of middle ear cavity; narrowing RW; narrow tympanic cavity; ossicular chain fixation via ankylosis of malleus to attic or of stapes to promontory	None	Ocular proptosis; hypertelorism; hypoplasia of the maxilla; parrot-like nose; craniosynotosis
DiGeorge syndrome **(AR)**	Malformed low-set ears; low-set pinna; atresia of EAC	Partial atresia of tympanic cavity; absent OW; absent stapedius muscle; absent or deformed ossicles; small facial nerve	High incidence of Mondini malformation; varying degrees of aplasia/dysplasia of cochlea; absent LSCC; hypoplastic seventh and eighth nerves	Congenital absence of parathyroid and thymus gland; heart and kidney abnormalities
Frontometaphyseal dysplasia (Gorlin-Holt syndrome) **(Otoskeletal)**	None	Deformed ossicles	Osseous infiltration around cochlea	Large supraorbital ridge; absent pneumatization of the frontal sinuses; micrognathia; metaphyseal splaying of the tubular bones; wide nasal bridge; flaring of the iliac wings
Goldenhar's syndrome (oculoauriculovertebral dysplasia) **(Otocervical or Multifactorial Disorder)**	Preauricular appendages; deformed auricle, atresia of canal	Severe dysplasia with narrow cavity; absent ossicles; straightened tensor tympani muscle running past an absent cochleariform process; poor development of stapedius muscle; absent chorda tympani nerve; hypoplasia OW and facial nerve	Hypoplastic cochlea and petrous ridge; short IAC with acute upward inclination; shortened LSCC and SSCC	Epibulbar dermoids; hemi- or block vertebrae; unilateral hypoplasia of maxilla/mandible; coloboma of upper lid; pharyngeal anomalies
Hemifacial microsomia **(Otocraniofacial or Multifactorial Disorder)**	Microtia; atresia/stenosis of EAC; vertically oriented EAC	Descent of tegmen; ossicles deformed or absent	None	Unilateral mandibular/maxillary hypoplasia; macrostomia; hypoplastic TMJ; hemivertebrae or hypoplasia; coloboma of upper lid
Klippel-Feil syndrome **(Otocervical or AR)**	Low-set ears; microtia; atresia/vertical orientation of EAC	Absent ossicles; thickening and fixation of stapes; bony obliteration of tympanic cavity	High incidence of Mondini malformation; range from hypoplasia of cochlea and SCCs to a simple otocyst; stenotic IAC	Short neck; fusion of two or more cervical vertebrae; low occipital hairline
Mixed deafness with perilymph gusher during stapes surgery (or X-linked progressive mixed hearing loss) **(X-Linked Recessive)**	None	Congenital fixation of stapedial footplate	Dilation of lateral part of IAC; thin osseous separation between lateral end of IAC and vestibule/basal turn of cochlea	Widening of labyrinthine facial nerve canal; abnormal cochlear size
Moebius syndrome (congenital facial diplegia) **(AR)**	Auricular malformation; microtia; slight EAC atresia	Facial canal absent, with no enlargement at geniculate ganglion; ossicular mass without identifiable stapes, OW or RW	SCC and vestibule dilated; hypoplastic cochlea, which may be a cystic cavity	Facial and abducens nerve palsies; possible additional cranial nerve involvement
Osteogenesis imperfecta (van der Hoeve's syndrome) **(Otoskeletal or AD, with Variable Expressivity and Incomplete Penetrance)**	None	Stapes abnormalities	Loss of otic capsule (changes identical to those of cochlear otosclerosis)	Deformity and bending of extremities; short stature; hyperextensibility of ligaments; dental defects; blue sclera; fine hair; thin cornea

Table 21-1
SYNDROMES WITH CONGENITAL ABNORMALITIES OF THE EAR *Continued*

Syndrome	Ear Abnormalities (Outer)*	Ear Abnormalities (Middle)*	Ear Abnormalities (Inner)*	Major Associated Anomalies
Osteopetrosis (Albers-Schonberg disease) **(Otoskeletal or AD, AR, or Sporadic)**	Narrowed canal	Persistent stapedial artery; fetal form of stapes; abnormal malleus/incus; sclerotic bone with narrowing of the facial canal and typanic cavity and covering of the OW and RW; obliteration of mastoid air cells	IAC narrowed	Generalized increase in bone density with narrowed neural foramina; obliterated paranasal sinuses and mastoid air cells; fractures; anemia; facial paralysis
Pendred's syndrome **(AR)**	None	None	High incidence of Mondini malformation; incompletely developed cochlea with hypoplasia; flattening of promontory	Triad of goiter, malformed inner ear vs. congenital SNHL, and pathologic perchlorate test
Pierre Robin syndrome (cleft palate, micrognathia, and glossoptosis) **(Otocraniofacial or AD)**	Cup ears; low-set ears	Thickened stapes, crura and footplate; small facial nerve; dehiscent facial canal; absent middle ear	Scala communis between apical and middle cochlear turns; small modiolus; small IAC	MR; hydrocephalus; microcephaly-microphthalmia; myopia—congenital cataracts; esotropia; retinal detachment; sixth nerve palsy; Moebius syndrome; cleft palate—hypoplastic mandible; congenital heart disease; spina bifida; syndactyly
Refsum syndrome (heredopathia atactica polyneuritiformis) **(AR)**	None	None	Cochleosaccular atrophy reported; thickening about peripheral nerves by concentrically arranged lamellae of connective tissue; no known radiographic abnormality	Hearing loss; retinitis pigmentosa; cerebellar ataxia; peripheral neuropathy; cardiac myopathy; congenital ichthyosis
Thalidomide embryopathy **(Teratogen; Iatrogenic Ototoxicity)**	Complete absence of auricle; atresia of canal	Forwardly displaced mastoid process; contracted tympanic cavity; absent, fixed, or abnormally situated ossicles	Range from saccular dilation of LSCC to severe dysplasia of the otic cystic remnant	Varying degrees of limb reduction defects; cardiac anomalies; deafness; gastrointestinal malformations; hemangiomas; cranial nerve palsies
Treacher-Collins syndrome (mandibulofacial dyostosis) **(Otocraniofacial or AD)**	Deformed, low-set auricles; varying degrees of stenosis or atresia of EAC	Deformed or absent ossicles; decreased size of middle ear cavity; underdeveloped mastoids; abnormal course of the facial nerve (usually anteriorly displaced)	Occasional abnormal vestibule with a short, wide LSCC; large CA	Antimongoloid slant of palpebral fissures; coloboma of internal third of lower lid; malar/mandibular hypoplasia; scalp hair projecting onto side of face
Trisomy 13–15 (Patau syndrome) **(Chromosomal)**	Low-set, malformed ears; stenotic EAC; small TM	Thick manubrium; distorted incudostapedial joint; deformed stapes; small facial nerve; wide angle of facial genu; absent stapedial muscle and tendon; absent pyramidal eminence; absent or small antrum; small mastoids	Distorted/shortened cochlea; absent cochlear hook; malformed apical cochlear turn; absent or underdeveloped modiolus; large/patent cochlear duct; widened LSCC; narrowed PSCC; short/straight ELD; shallow/wide IAC; scala communis between apical and middle and between middle and basal cochlear turns	Microcephaly and arrhinencephaly; multiple eye anomalies; hypertelorism, cleft lip and palate; VSD/abnormal palm print; simian creases/hyperconvex nails
Trisomy 18 syndrome (Edwards syndrome) **(Chromosomal)**	Low-set/deformed ears; atretic EAC	Deformed malleus/ incus; columella type or fetal form of stapes; split tensor tympani muscle; exposed stapedial muscle; absent stapedial tenon; hypoplastic facial nerve; abnormal course of facial and chorda tympani nerves; absent pyramidal eminence	Hypoplastic modiolus; scala communis betweem apical and middle turns; ELD increased; double singular nerve; absent lateral limb of SSCC and crista and lateral limb of LSCC	Ptosis of eyelids; high-arched palate; micrognathia; flexion deformities; hypertrophic pancreas

Table 21-1
SYNDROMES WITH CONGENITAL ABNORMALITIES OF THE EAR *Continued*

Syndromes	Ear Abnormalities (Outer)*	Ear Abnormalities (Middle)*	Ear Abnormalities (Inner)*	Major Associated Anomalies
Trisomy 21 (Down syndrome) **(Chromosomal)**	Small, malformed, low-set pinnae; EAC stenosis	Mesenchymal remnants; wide angle of facial nerve genu; bulky malleus/incus with bone marrow; deformed stapes and distorted crura; underdeveloped pyramidal eminence; high jugular bulb; poorly developed mastoids	Shortened cochlea; wide utricle and SCCs; wide CA; small PSCC; enlarged bony posterior canal ampulla	Hypertelorism; epicanthic fold; slanting eyes; strabismus; narrowed nasal space; hypoplastic paranasal sinuses; protruding tongue; high palate; flattened skull; VSD/ASD, PDAs, situs inversus; MR
Usher's syndrome **(AD, AR, or X-Linked Recessive)**	None	None	Atrophic changes of the organ of Corti and spiral ganglia in the basal turn; milder degrees of atrophy of stria vascularis, limbus, tectorial membrane, and Reissner's membrane reported; no known radiographic abnormality	Hearing loss; retinitis pigmentosa; vestibulocerebellar ataxia; mental retardation
VATER (vertebral defects; anal atresia; tracheoesophageal fistula; renal anomalies **(Unknown Mode of Inheritance)**	None	Hypoplasia of facial nerve, chorda tympani nerve, and greater superficial petrosal nerve; decreased geniculate ganglion secondary to decreased number of cells; anterior curvature of stapes superstructure; hypertrophic anterior annular ligament	Irregular course of LSCC; superior utricle; superior saccule; enlarged ELD and ELS	Vertebral defects; anal atresia; Tracheoesophageal fistula; esophageal atresia; renal defects; radial limb hypoplasia; large fontanelles; cardiac defects; single umbilical artery; genital anomalies
Waardenburg syndrome **(AD)**	None	None	PSCC absent; LSCC slightly dilated; vestibule slightly irregular in shape	Hypertelorism; broad, high nasal root; white forelock; pigmentary disorders of the eye
Wildervanck syndrome (cervicooculoacoustic syndrome) **(Otocervical or Sex-Linked Disorder)**	Preauricular tags; posteriorly displaced pinnae; small, deformed ears; hypoplasia and absence of EAC	Rudimentary ossicles; fusion of malleus/incus; absent stapes and OW; fixation of stapes; ossified stapedius tendon	Aplasia or hypoplasia of various structures; abnormal SCCs; bony septum in IAC	Manifestation of Klippel-Feil syndrome plus deafness; abducens palsy; and retraction of the orbits

AD, autosomal dominant; *AR,* autosomal recessive; *ASD,* atrial septal defect; *CA,* cochlear aqueduct; *EAC*, external auditory canal; *ELD,* endolymphatic duct; *ELS,* endolymphatic sac; *IAC*, internal auditory canal; *LSCC*, lateral semicircular canal; *OW,* oval window; *PDA,* patent ductus arteriosus; *PSCC*, posterior semicircular canal; *RW,* round window; *SCC*, semicircular canal; *SSCC,* superior semicircular canal; *TC,* tympanic cavity; *TM,* tympanic membrane; *TMJ*, temporomandibular joint; *VSD,* ventricular septal defect.

The internal auditory canal (IAC) may be normal in the presence of a grossly deformed inner ear. Conversely, cases of dysplasia or aplasia of the IAC may occur in the presence of a normal labyrinth. However, extreme hypoplasia or aplasia of the IAC is associated more commonly with significant bony malformations of the inner ear. The development of the IAC is distinct from that of the labyrinth, and the underlying mechanism explaining the coexistence of these congenital deformities is not apparent.

Anatomic variations include a range of dimensions, contours, and spatial orientations of the structures within the temporal bone region encountered in a normal population with neither functional impairment nor anatomic substrate carrying the potential for imperiling the well-being of the individual. These two criteria provide the crucial distinction between a variation and an anomaly.[1]

Complete descriptions of the embryology and anatomy of the various parts of the ear are presented in Chapter 19. Concepts important to this discussion are briefly summarized in the appropriate sections.

ANOMALIES OF THE OUTER EAR

The outer ear is composed of the auricle and the external auditory canal (EAC). The auricle develops from tissues of both the first (mandibular) and second (hyoid) branchial arches. The EAC develops from the first branchial cleft, which forms between the first and second branchial arches. In the sixth fetal week, the cleft invaginates. The tympanic cavity is formed in the fourth fetal week from invagination of the first pharyngeal pouch. The meeting of these two invaginations results in formation of the primitive tympanic membrane. These two invaginations are temporarily separated by a core of epithelial cells that is later canalized in the twenty-sixth fetal week. Partial or complete failure of this

canalization results in stenosis or atresia of the EAC, respectively.[5]

Malformations of the outer ear are referred to as congenital aural dysplasias (CAD). A malformation of the auricle alone is referred to as microtia. CAD has been estimated to occur in 1 of 3300 to 10,000 births, with a higher incidence of 1 in 900 reported in the era of thalidomide embryopathy. CAD is most commonly isolated, without known cause, and unilateral. The right ear is more commonly affected, and in up to one third of cases, CAD may be bilateral.[6] CAD may also occur in conjunction with other organ abnormalities due to genetic disorders, chromosomal aberrations, intrauterine infections, and environmental teratogens.[7]

A classification system developed by Weerda et al. divides the deformites into first, second, and third degrees. The third degree is the most pronounced deformity and is defined as either absence of normal auricular structure (anotia) or severe dysplasia of the auricular soft tissues, with possible inferior displacement due to incomplete ascension from the neck. With first or second degree dysplasias, the EAC is commonly stenotic. With third degree auricular dysplasias, the EAC is commonly atretic.[7]

EAC malformations may be fibrous, bony, or both (Fig. 21-1). In the fibrous type, there is a soft-tissue plug where the tympanic membrane (TM) should be. In the bony type, there is a bony plate where the TM should be.[6, 7] The thickness of the bony plate is variable and reaches 31 mm.[7] Stenotic EACs often have a more superiorly angulated course than normal, extending from inferolaterally to superomedially (Fig. 21-2). With stenosis or atresia, there is an increased incidence of both primary (congenital) and secondary (acquired) cholesteatomas or epidermoids (Figs. 21-3 and Fig. 21-4). These may occur in the stenosed EAC or deep to the atretic plate in the middle ear cavity.

Associated Middle Ear and Ossicular Abnormalities

Middle ear abnormalities tend to occur concomitantly with CAD because of the common embryologic origins of the EAC and middle ear. The ossicular chain, with the exception of the footplate of the stapes, develops from the first and second branchial arches. The tympanic cavity develops from the first pharyngeal pouch.[5] Ossicular deformities include dysplasia, decreased size, abnormal rotation, and absence of the malleus and incus. There can be deformity of the malleoincudal and incudostapedial articulations, as well as fusion of the malleus and incus to the attic wall. More severe CADs tend to have more severe ossicular abnormalities. Abnormalities of the stapes are less common and do not directly correlate with the degree of CAD because of the dual origin of the stapes from the second branchial arch and the otic capsule.[6]

Pneumatization of the middle ear cavity is often reduced in CAD, with the extent of reduction correlating directly with the severity of the dysplasia. Although pneumatization of the entire middle ear can be affected, the hypotympanum is usually most severely reduced.[7]

Other Associated Abnormalities

Other osseous abnormalities may occur with CAD including aplasia or hypoplasia of the tympanic part or

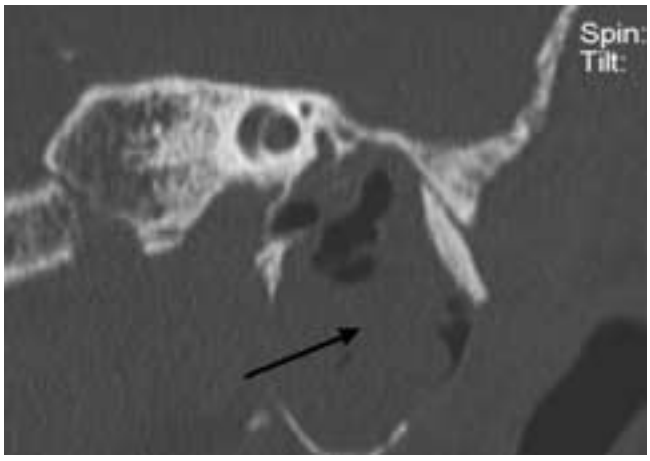
mastoid process of the temporal bone, deformity of the temporomandibular joint (TMJ), and defects in the zygomatic arch. The severity of hypoplasia of the tympanic part or mastoid process of the temporal bone correlates with the degree of auricular dysplasia. Pneumatization of the mastoid is often reduced, in turn affecting the position of the sigmoid sinus.[7] The mandibular condyle is frequently dysplastic, and the joint space is often shallow.[8] The temporal squama may be pushed down and the glenoid fossa may be markedly flattened or even absent.[9] The joint position is frequently abnormal, being relatively higher and more posterior in relation to the middle ear. Rotation or elevation of the carotid canal, as well as hypoplasia or aplasia of the internal carotid artery, may also occur.[7]

The facial nerve canal frequently has an anomalous course in patients with CAD. The tympanic and mastoid segments are most commonly affected, with rare involvement of the labyrinthine segment. The tympanic segment is typically displaced caudally, extending as inferiorly as the round window. It may also be dehiscent and medially displaced, overlying the oval window and/or passing between the crura of the stapes. The mastoid segment is usually displaced anterolaterally, with the facial nerve exiting the temporal bone at the level of the round window.[6, 7] In some cases, the nerve may exit the skull base in a narrow space between the glenoid fossa and the mastoid process.

The oval and round windows may be absent in CAD, although isolated absence of the oval window is more common. Absence of either window does not correlate directly with the degree of dysplasia.[7] When there is CAD or underdevelopment of the first arch structures, there is compensatory anterior shifting of the second arch structures including the stapes superstructure. As a result, the stapes does not make appropriate contact with the otic capsule. Such contact is thought necessary for induction of formation of the oval window.[10]

Anomalies of the inner ear and IAC are rarely associated with CAD. In one study of atretic patients, 12% (8 of 66) had a radiographically detectable inner ear abnormality.[11] Inner ear anomalies include hypoplastic cochleas (5%), hypoplasia or enlargement of the lateral semicircular canal (most common, 10%), and/or enlargement of the vestibule and vestibular aqueduct. The IAC may have an anomalous orientation extending from superomedially to inferolaterally and may be hypoplastic.[7]



VIEW IMAGE

FIGURE 21-4 EAC atresia with cholesteatoma. Coronal CT image showing a large cholesteatoma expanding the EAC and middle ear cavity (*black arrows*) in a patient with EAC atresia. A spontaneous fistula formed between the cholesteatoma and the skin (not shown).

Surgical Considerations

The surgical approach for correction of aural atresia, as defined by Jahrsdoerfer et al., is an anterior approach that involves drilling through bone in close proximity to the TMJ anteriorly, the middle cranial fossa superiorly and the mastoid posteriorly.[12] Yeakley and Jahrsdoerfer[13] devised a 10-point CT preoperative evaluation of aural atresia to help estimate the likelihood of a favorable surgical outcome. In this system, the EAC, malleus, incus, and their respective joints; the oval and round windows; the middle ear and mastoid pneumatization; and the facial nerve course are evaluated.

The presence of the stapes is given most importance. The course of the facial nerve is also critical, as marked anterior migration of the mastoid segment would likely result in injury at the time of surgical repair. The presence and width of the mastoid antrum and the middle ear are important for surgical accessibility. Patients with scores of 5 or less are not considered for surgery, and patients with scores of 8 or more have an 80% chance of having their hearing restored to almost normal levels. Cochlear function must be intact, as assessed clinically, and CT must show a normal inner ear to qualify for surgery. A deformed cochlea associated with CAD is more vulnerable to injury from vibratory trauma at surgery, with an increased risk of inducing sensorineural hearing loss.[14] The optimal timing of surgical correction, as agreed on by most authors, is between 5 and 8 years of age since mastoid development is complete by that time.

ANOMALIES OF THE MIDDLE EAR

Isolated anomalies of the ossicles and middle ear without EAC stenosis or atresia do occur but are much less common than those of the outer ear. Autosomal dominant inheritance has been reported in some cases. These anomalies may also be found in association with a variety of syndromes, the more common of which are Goldenhar and Treacher-Collins syndromes.[15] Depending on the source, either the incus or stapes are the ossicles most frequently malformed or absent.[15, 16] Anomalies of the incus include aplasia, fusion of the short process to the lateral semicircular canal, shortening or malformation of the long process, absent incudostapedial joint, and fibrous union of the joint. Stapes anomalies include aplasia, absence of the head and crura, hypoplasia or a fetal form, a columnar-type deformity, fusion of the head to the promontory, and footplate fixation. Anomalies of the malleus include aplasia, deformed head, triple bony union of the handle (manubrium) with the long process of the incus and stapes head, and fusion of the incudomalleal joint. A rare anomaly of the malleus is congenital fixation of the head to the lateral epitympanic wall called the malleus bar (Figs. 21-5 and 21-6).[17, 18] This

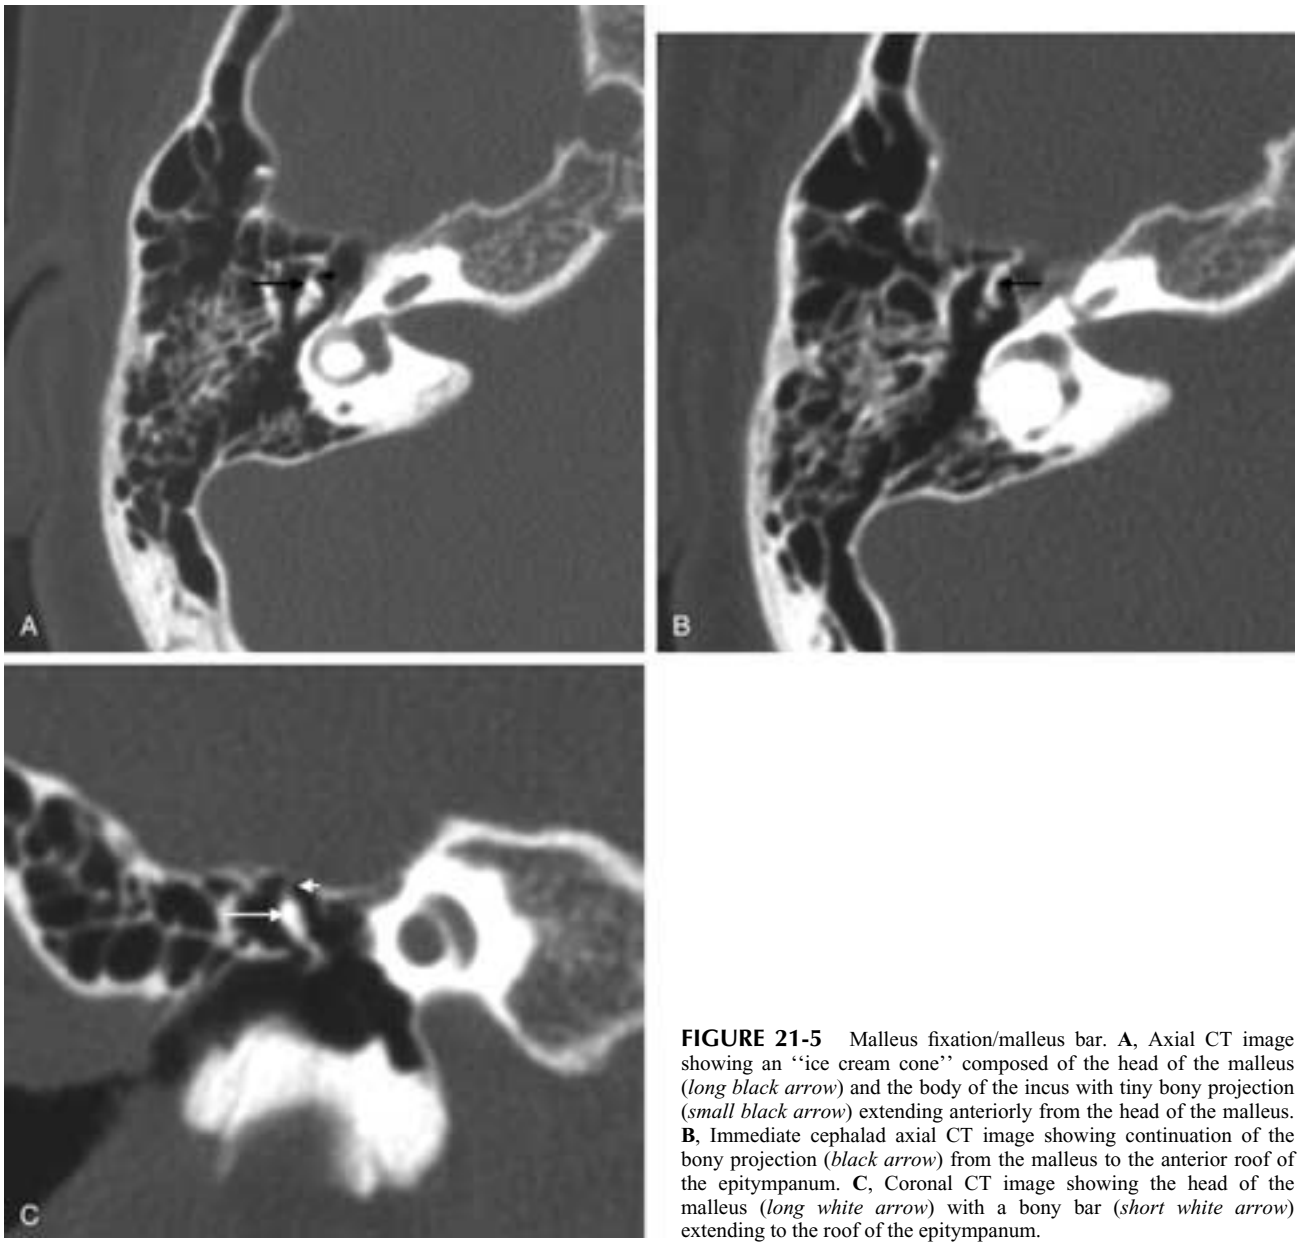

FIGURE 21-5 Malleus fixation/malleus bar. **A**, Axial CT image showing an ''ice cream cone'' composed of the head of the malleus (*long black arrow*) and the body of the incus with tiny bony projection (*small black arrow*) extending anteriorly from the head of the malleus. **B**, Immediate cephalad axial CT image showing continuation of the bony projection (*black arrow*) from the malleus to the anterior roof of the epitympanum. **C**, Coronal CT image showing the head of the malleus (*long white arrow*) with a bony bar (*short white arrow*) extending to the roof of the epitympanum.

VIEW IMAGE

may also involve fixation of the incus body.[17] Isolated fixation of the incus to the scutum has been reported and is likely an even rarer phenomenon.[16]

The ossicles and the ossicular chain may not only be absent or malformed, but may also have anomalies classified as those of ''delayed disappearance.''[15] These anomalies include preservation of embryologic structures such as bone marrow and mesenchymal tissue within the ossicles beyond 25 months of age. Normally, bone marrow is present in the head of the malleus and the body of the incus at birth and persists up to 25 months of age. It is gradually converted to bone and vascular channels. The marrow may have a role as hematogenous tissue in infancy. After 25 months, the presence of marrow is no longer normal.[19] The most frequently reported abnormalities of this kind are a large bone marrow cavity in the incus or malleus and an incus largely composed of mesenchymal tissue. These anomalies may occur with Treacher-Collins syndrome and trisomy 13.[15]

The facial nerve course is often anomalous in the presence of ossicular chain anomalies as the ossicles develop from the first and second branchial arches and the nerve develops from the second arch. The most common facial nerve anomalies noted to occur in patients with congenital middle ear malformations without stenosis or atresia of the EAC are displacement and wide bony dehiscence of the tympanic segment (Fig. 21-7).[15, 20] The nerve is typically displaced inferiorly and medially, and often either crosses the oval window, lies inferior to it, or is in apposition to the stapes. Less commonly, the tympanic and mastoid segments may be laterally displaced.[15] The tympanic segment has also been described in cases of dehiscence as being freely suspended in the aerated middle ear cavity.[20] More proximally, the first genu of the nerve

Copyright © 2003, Mosby, Inc. All rights reserved.

may have an abnormally wide (obtuse) angle.[15] Anomalies of the chorda tympani and greater superficial petrosal nerve may occur in conjunction with facial nerve anomalies and include an enlarged chorda tympani nerve.[15, 20]

Often associated with a dehiscent facial nerve that overlies the oval window and/or stapes is congenital absence of the oval window (Fig. 21-8). Many authors feel that the anomalous position of the facial nerve acts as a mechanical barrier to the stapes, preventing it from making appropriate contact with the developing otic capsule at the future oval window site. As such, oval window development is not induced. Theoretically, less interference by the facial nerve would result in partial absence or hypoplasia of the oval window. This theory is supported by the fact that other anomalies of the inner ear are extremely rare in cases of congenital absence of the oval window, a derivative of the inner ear.[10, 21, 22] Of note, isolated atresia of the oval window may also occur in the absence of facial nerve dehiscence (Fig. 21-9).

Lastly, other anomalies that may occur within the middle ear include an absent stapedius muscle and/or tendon, absence or elongation of the pyramidal eminence, and hypoplasia of the tympanic cavity.[23] Cholesteatomas may also occur as congenital lesions within the middle ear cavity without associated stenosis or atresia of the EAC (Fig. 21-10).

ANOMALIES OF THE INNER EAR

Congenital inner ear anomalies represent a wide range of pathologies that have had variable classifications over the years. The original classification of these anomalies was by discrete patterns of histopathologic change described by various investigators.[24] These included the Bing-Siebenmann (BS), Scheibe, Mondini, Alexander, and Michel-type dysplasias. BS dysplasia is characterized by anomalies of the cochlear and vestibular components of the membranous labyrinth. In the cochlea, a rudimentary mound of undifferentiated cells replaces the organ of Corti, against which Reisner's membrane is collapsed. In Scheibe's dysplasia, abnormalities are limited to the saccule and cochlea and include stria vascularis atrophy, a deformed tectorial membrane, and a poorly differentiated organ of Corti, against which Reisner's membrane is collapsed. Scheibe's dysplasia is the most commonly observed temporal bone dysplasia in cases of profound congenital sensorineural hearing loss.[25] Mondini dysplasia is characterized by a normal basilar turn but a decreased number of upper turns, with modiolar hypoplasia and absence of the interscalar septum. The upper turns are represented by a sac-like remnant. Alexander's deafness is characterized by underdevelopment of the basilar turn. Michel dysplasia is complete absence of the labyrinth including absence of the sensorineural structures of the inner ear. Other authors[3] have simply classified inner ear anomalies into Scheibe and Mondini dysplasias and anomalies associated with chromosomal disorders, stating that the BS and Alexander types have been inadequately documented and that the Michel type is too rare to be of any clinical significance. Jackler proposed a classification system based on the hypothesis that the various inner ear anomalies result from an arrest of maturation during different stages of inner ear embryogenesis.[32]

None of these classification systems, however, is all-inclusive. There are anomalies that have been and continue to be documented with thin-section, high-resolution CT and MR imaging that do not fit neatly into any particular system. Therefore, in this section, the various inner ear anomalies that have been documented radiographically will be presented and related to a particular classification system when possible.

Imaging Techniques

In many institutions, CT of the temporal bone remains the method of choice for the evaluation of congenital inner ear malformations. CT is readily able to define the bony labyrinth and give information regarding concomitant middle and external ear anomalies. Alternatively, thin-section, high-resolution MR imaging of the inner ear, which can be achieved with both gradient-echo and fast spin-echo T2-weighted techniques, gives exquisite detail of the membranous labyrinth, in which there may be anomalies not necessarily associated with anomalies of the bony labyrinth. For example, MR imaging allows differentiation between the scala tympani and scala vestibuli. In patients with congenital inner ear malformations requiring cochlear implantations, fibrous obliteration of the scala tympani and scala vestibuli has been shown with T2-weighted gradient echo imaging. Scalar asymmetry with enlargement of the scala vestibuli and media has been shown with fast spin echo T2-weighted techniques.[26] MR imaging also provides the ability to diagnose aplasia or hypoplasia of the vestibulocochlear nerves. With high-resolution imaging in the sagittal plane, the cochlear nerve may be defined separately from the superior and inferior vestibular nerves and from the facial nerve within the IAC. Malformations of Reisner's membrane and the organ of Corti are too small to be detected, and the complete membranous labyrinth dysplasia occuring in BS dysplasia remains below the resolving capabilities of MR imaging. To date, MR imaging has been unable to identify the abnormalities in patients with Scheibe dysplasia.

Copyright © 2003, Mosby, Inc. All rights reserved.

Similarly, in Usher's, Refsum's, and Cockayne's syndromes, the abnormality is considered membranous and imaging is not likely to be abnormal. However, these patients have coexistent eye pathology such as retinitis pigmentosa (Usher's and Refsum's syndromes) or retinal degeneration (Cockayne's syndrome), so imaging is not crucial to making the diagnosis. However, very few of these patients have been examined with MR imaging, and it is possible that some abnormalities might be documented if MR imaging were used routinely (Fig. 21-11).

Imaging of the temporal bone with CT can be performed with both nonspiral and spiral techniques. With nonspiral techniques, a slice thickness of 1 mm is acceptable for images acquired in both the axial and coronal planes. Alternatively, with spiral techniques, images may be acquired using 0.5 mm collimation. The images can be

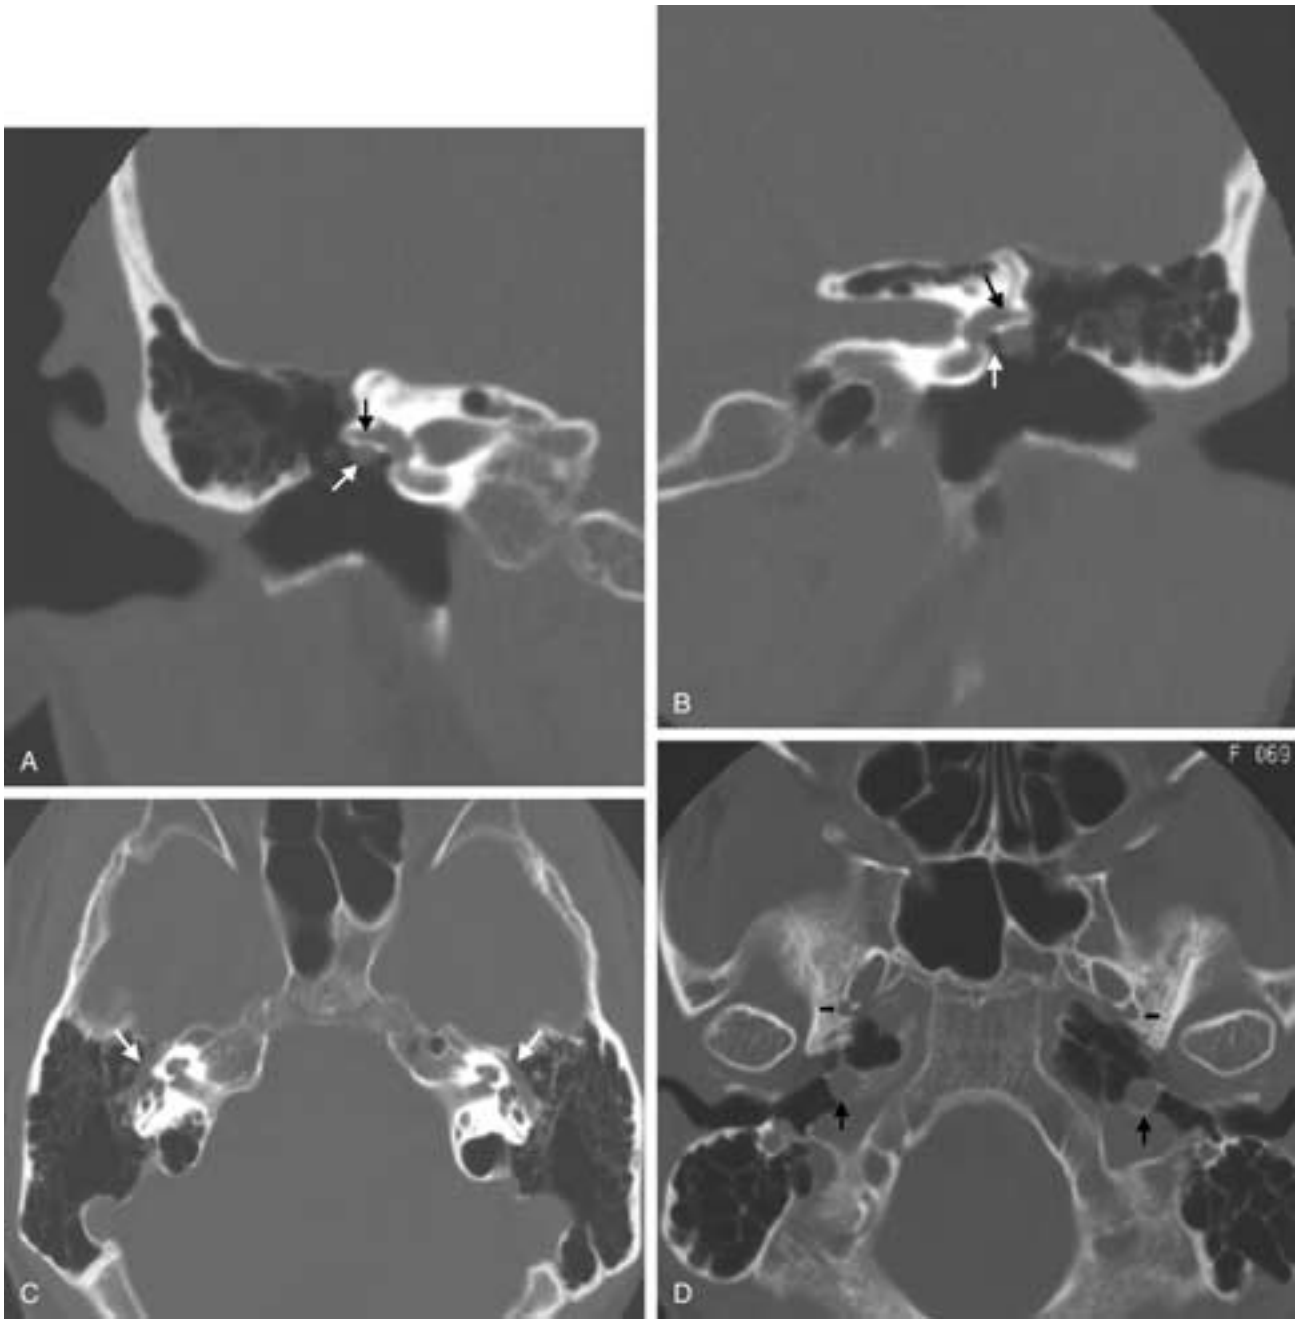

FIGURE 21-7 Dehiscent facial nerve. **A** and **B**, Right and left coronal CT images showing soft-tissue prominence in the middle ear cavity immediately inferior to the lateral semicircular canal (*black arrows*) in the expected location of the tympanic segment of the facial nerve (*white arrows*). No bony canal for tympanic segments consistent with dehiscence is identified. **C**, Axial CT image showing bilateral facial nerve dehiscence (*white arrows*). **D**, Axial CT image showing normal carotid canals (*long black arrows*) and presence of the foramen spinosum (*short black arrows*), indicating that the prominent soft tissue at the expected location of the tympanic facial nerve is not a persistent stapedial artery.

FIGURE 21-8 Inferior migration of the facial nerve, absent stapes, and stenotic oval window. **A**, Coronal CT image showing inferior migration of tympanic segments of the facial nerve (*white arrow*) approaching the stenotic oval window (*black arrow*). The stapes is absent. **B**, Axial CT image showing a low-lying tympanic segment of the facial nerve (*white arrow*) in the middle ear cavity. Note the handle of the malleus (*white block arrow*) on the tympanic membrane.

reconstructed with a slice thickness of less than 1 mm. This technique also provides submillimeter coronal reformatted images, which may obviate the need for direct coronal scanning. With these images, greater anatomic detail can be achieved and, as a result, more subtle anomalies may be revealed. The coronal reformatted images are true coronal images exactly perpendicular to the axial plane of acquisition so that the petrous ridge is viewed tangentially rather than obliquely. This may be useful, for example, when assessing the integrity of the tegmen tympani and when evaluating for possible dehiscence of the superior semicircular canals.

With MR imaging, routine 2 to 3 mm thick contiguous T1-weighted spin-echo images before and after intravenous gadolinium contrast administration may detect some congenital inner ear malformations. Thin T2-weighted gradient echo or spin echo images are more sensitive and may detect other congenital inner ear malformations. In one study, the T1-weighted images showed only portions of the congenital malformations, and the malformations were not visible in 40% of the patients. Nearly all anomalies were recognized on the thin gradient echo images.[27] Since the whole membranous labyrinth is only approximately 12 mm high and 10 mm wide, sections less than 1 mm thick must be used to study this small structure. Good in-plane spatial resolution and optimal contrast between the intralabyrinthine fluid and surrounding bone and nerves are required. Heavily T2-weighted gradient echo or spin echo images can provide such images with bright intralabyrinthine fluid and dark surrounding bone and nerves. Several gradient echo techniques including three-dimensional Fourier transform fast imaging with steady precession (3DFT-FISP), 3D-gradient-recalled acquisition in the steady state (GRASS), and constructive interference in the steady state (3DFT-CISS) have proven valuable in the study of the membranous labyrinth and IAC.[28, 29] The parameters may vary with the technique. However, by using small fields of view of 95 to 100 mm, high matrices of 256 × 512, and slice thicknesses of less than 1 mm, the acquisition of images with very high spatial resolution of, for example, 0.49 × 0.37 mm may be achieved. The ability to acquire MR images in multiple planes, and the use of multiplanar reconstructions and 3D maximum intensity projections (MIP), further facilitate the detection and detailed evaluations of inner ear malformations. Davidson et al.[26] have obtained high-resolution images of the membranous labyrinth by employing a surface coil placed over the EAC and a fast spin echo T2-weighted technique with a slice thickness of 2 mm. Their protocol consists of a small field of view of 20 × 10 cm, triple interleaved acquisition, and a matrix of 512 × 512.

Membranous and Bony Labyrinthine Anomalies

Semicircular Canals

Malformation of the lateral semicircular canal is one of the most common inner ear anomalies.[30–32] Malformation of the superior and posterior semicircular canals without involvement of the lateral canal is unusual, as the lateral semicircular canal is the last to form embryologically. The malformed canals are either narrow or, more commonly, are short and wide. In extensive malformations, the vestibule is dilated and forms a common lumen with the lateral canal. This anomaly may be called a lateral semicircular duct–vestibule dysplasia or a common utriculosaccular–lateral semicircular duct cavity. In some cases, it may not be possible to identify the canals because the lumen is obliterated or the canal is absent. When the canal is absent, there is a typical flattening of the corresponding portion of the otic capsule.[31]

The correct diagnosis can be made with thin-section CT of the temporal bone and with thin-section, T2-weighted gradient echo or fast spin echo MR imaging. The correct diagnosis can be missed on routine T1-weighted images because of poor contrast resolution and volume-averaging artifacts. The deformity has a variable appearance, and imaging may reveal a common utriculosaccular-lateral semicircular duct or short, wide semicircular ducts or

narrowing of the semicircular ducts (Figs. 21-12 to 21-19). This deformity may be bilateral and may be associated with other inner ear malformations (Fig. 21-16).

Semicircular duct aplasia is far less common than dysplasia. The deformity may be bilateral and may occur in combination with a normal or near-normal cochlea. The first cases of this entity were reported by Parnes and Chernoff.[33] If such an anomaly were caused by arrested development, the cochlea should also be malformed. Thus, occasionally, a specific aberration may occur, halting further development at a confined level.[30] Absence of all semicircular ducts is known to occur frequently in patients with CHARGE syndrome (Fig. 21-20 and Table 21-1). Isolated aplasia of the posterior semicircular duct has been described in patients

FIGURE 21-19 Partial absence of the posterior semicircular canal. **A**, Axial T2-weighted gradient-echo image through the right inner ear. A normal vestibule (*V*) can be seen. The cochlea is too small; the apical and second turns (*long white arrow*) are developed but are too small. A large endolymphatic duct/sac can be recognized (*white arrowheads*). The posterior semicircular duct cannot be seen; there is no high signal intensity at the site where the duct should be (*small white arrow*). **B**, Axial T2-weighted gradient-echo image through the left inner ear. Hypoplasia of the apical and second turns of the cochlea can again be appreciated (*long white arrow*). High signal intensity fluid can be seen in the posterior semicircular duct on the left side (*small white arrow*), and the endolymphatic duct has a normal size (*white arrowhead*). Normal vestibule (*V*). **C**, Three-dimensional virtual image of the right membranous labyrinth, made by using 0.7 mm thick T2-weighted gradient-echo images. The interruption of the posterior semicircular duct can be recognized (*small white arrows*). The large endolymphatic duct/sac can be seen (*white arrowheads*). The apical turn (*black arrowhead*) and the second turn of the cochlea (*small black arrow*) are slightly hypoplastic, but the basal turn (*long white arrows*) is severely hypoplastic (compare this with the normal cochlea in Figs. 21-15C, D and 21-17B, and especially with the same view in Fig. 21-51F). Normal lateral (*long black arrow*) and superior (*large black arrow*) semicircular ducts. The middle part of the posterior semicircular canal also cannot be seen on CT (not shown). This excludes fibrous obliteration of this segment of the canal. Labyrinthitis ossificans involving the posterior semicircular canal cannot be excluded. However, the association with several other congenital malformations, the absence of other obliterations or calcifications of the membranous labyrinth, and the normal aeration of the adjacent middle ear and mastoid all support the diagnosis of congenital absence of the middle part of the posterior semicircular duct.

with Waardenburg's and Alagille's syndromes.[34] Patients with semicircular duct aplasia may present with vertigo or abnormal findings during vestibular testing, and there is absence of fluid-filled semicircular ducts on MR imaging (Fig. 21-19). Occasionally, the lumen of a semicircular duct may be partially or completely obliterated with fibrous or calcified tissue, which may give the impression of aplasia on MR imaging. Therefore, confirmation of the absence of the semicircular canals with CT may be necessary for differentiation between aplasia and fibrous or calcified obliteration of the canals, as can be seen with labyrinthitis ossificans (Fig. 21-21).

Another presumed anomaly of the semicircular canals that has been described only recently with high-resolution CT of the temporal bone is dehiscence of the roof of the superior semicircular canal (SSCC).[35, 36] This defect can be best appreciated on coronal images through the temporal bone (Fig. 21-22). This anomaly may be associated with a clinical entity known as Tullio's phenomenon, which consists of sound-induced vertigo, nystagmus, or both. Normally, sound is transmitted from the stapes through the oval window into the cochlea, where the hair cells are activated, causing neural stimulation. The round window allows the sound pressure to dissipate and transmits it back to the middle ear. The semicircular canals do not normally have a window to dissipate pressure. Therefore, the pressure in the canals remains constant, without vibration of the related hair cells. However, the dehiscence of the roof of the superior semicircular canal acts as a ''mobile'' window and allows the sound pressure to be transmitted into the vestibular apparatus, stimulating the hair cells and producing vertigo.[37]

Vestibule/Utriculosaccular Structures

Anomalies of the vestibule or utriculosaccular structures rarely occur as an isolated event. More frequently, they are present in association with other inner ear anomalies.[38] As previously discussed, the vestibular/utriculosaccular anomalies often consist of complete (Fig. 21-15) or partial (Fig. 21-23) assimilation of the semicircular canals (usually the lateral semicircular canal) into the vestibule.[32] Occasionally, subtle enlargement or malformation of the vestibule (Figs. 21-23 and 21-24) and semicircular ducts can be detected on CT or MR imaging. Rarely, an enlarged globular vestibule may be found without assimilation of the semicircular canals. This anomaly of the inner ear has been associated with thalidomide-induced deafness.[38]

Cochlea

Jackler et al. proposed a classification system of cochlear anomalies based on their experience with radiographs (CT and polytomograms). In this system, each anomaly was proposed to be the result of an arrest of maturation or development of the cochlea at different stages of organogenesis.[32] Many of these cochlear anomalies, first identified radiographically with polytomography and then CT, have

also been identified with MR imaging. While many cochlear anomalies fit into this classification system, there are some that do not. These include cochleas with extra turns, cochlear duplications, and small ''dwarf''-type cochleas that are small or hypoplastic but do possess the normal number of turns.[24] These anomalies may result from ''aberrant'' rather than ''arrested'' development, according to Jackler et al. As well, since their classification system was based on anomalies detected by polytomography and/or CT, some of the cochlear anomalies recently described with MR imaging are difficult to place. For example, defects between the scala vestibuli/media and scala tympani can sometimes be the only detectable deformities in an otherwise normal bony labyrinth and cochlea. These changes may not be seen on CT and may be detectable only on high-resolution, T2-weighted gradient echo or fast spin echo images (Fig. 21-25).

The spectrum of cochlear anomalies as described by Jackler et al. ranged from early arrest of development, cochlear aplasia, to late arrest of development, cochlear partition defects (Figs. 21-26 to 21-28). At imaging these abnormalities can be classified approximately following Jackler et al.'s classification of cochlear anomalies:

- *Complete Labyrinthine Aplasia (Michel's Deformity).* In complete labyrinthine aplasia there is no inner ear development. In place of the normal inner ear structures, a small, single cystic cavity or several small cavities are present. This description corresponds to the histopathology classically described by Michel and represents an early failure in development correlating with the third gestational week. It is essentially an aplasia of the inner ear and is very rare.[3]
- *Common Cavity*. Arrested growth during the fourth fetal week results in a common cavity for the cochlea and vestibule. There is a large cystic cavity with no internal architecture. One fourth of all cochlear anomalies are common cavity malformations. The semicircular canals may be normal or malformed (Figs. 21-27 and 21-28).
- *Cochlear Aplasia*. Arrested development during the fifth week of embryogenesis produces aplasia of the

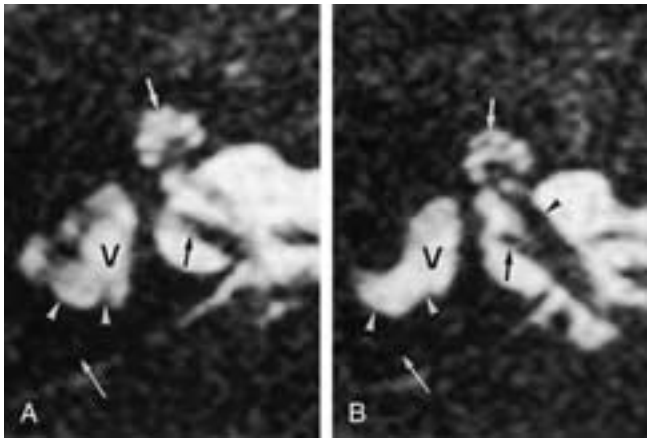
cochlea. The cochlea fails to form. The other elements of the inner ear (i.e., the vestibule and semicircular canals) may be normal or malformed.

- *Cochlear Hypoplasia*. Cochlear hypoplasia displays a small rudimentary cochlear bud associated with a normal or malformed vestibule and semicircular canals. Cessation of cochlear development during the sixth week of intrauterine life is the probable cause of this defect (Figs. 21-16, 21-19).
- *Incomplete Partition and Dilatational Defects (Including Classic Mondini's Dysplasia*). This entity represents a small cochlea with an incomplete partitioning of or absent interscalar septum. There is a basilar cochlear turn and a common cloaca or cavity where the middle and apical turns would normally occur. The abnormalities of the bony labyrinth in this anomaly can readily be identified on CT (Fig. 21-29), and the membranous abnormalities can be identified with T2-weighted gradient echo (Fig. 21-30) or fast spin echo MR images. Since the scala tympani and vestibuli can normally be shown as distinct structures on MR imaging,[29] the interscalar septal defects and the absence of the osseous spiral lamina of the middle and apical turns that result in a scala communis cochleae can be identified (Figs. 21-31 and 21-32). Anomalies of the remaining inner ear, such as dilatation of the vestibular aqueduct, may also be present. The vestibule and semicircular canals may be normal or malformed. Arrest of maturation at the seventh week of intrauterine life may result in this type of incomplete partition defect. Incomplete partition of the cochlea characterizes a classic histologic malformation first described by Mondini in 1791. Mondini documented a flat cochlea having 1½ turns instead of the normal 2½ to 2¾ turns. He also described a large vestibule.[39] Aside from Scheibe's deafness, Mondini's malformation is probably the most common form of genetic deafness.[40] A Mondini malformation is frequently present in patients with the branchio-oto-renal syndrome (Fig. 21-31).



VIEW IMAGE

FIGURE 21-23 Globular enlargement of the utriculosaccular structures in association with semicircular duct malformations. **A**, Axial 0.7 mm thick T2-weighted gradient-echo (3DFT-CISS) images through the upper part of the right utriculosaccular structures. Enlarged fluid-filled utriculosaccular structures can be seen inside the vestibule (*V*). The lateral semicircular duct (*white arrowheads*) is irregular and too thick and is partially incorporated in the large vestibule. The posterior semicircular duct is absent (*long white arrow*). Normal cochlea (*small white arrow*) and inferior vestibular branch of the VCN (*small black arrow*). **B**, Axial T2-weighted gradient-echo image through the inferior part of the utriculosaccular structures. The posterior part of the lateral semicircular duct is too large (*white arrowheads*). The posterior semicircular duct is absent (*long white arrow*), and the utriculosaccular structures inside the vestibule (*V*) are still a little too large. Normal cochlea (*small white arrow*), inferior vestibular (*small black arrow*), and cochlear (*black arrowhead*) branch of the VCN.

More subtle partition defects than the Mondini malformation have been described since the Jackler et al. classification system was first proposed. Included in this group are modiolar and interscalar septal defects. Lemmerling et al.[41] described the normal modiolus on high-resolution, thin-section CT as an ''hourglass-shaped, rectangular, triangular, or trapezoidal bony structure located along the central axis of the basal and middle turns of the cochlea.'' They described four distinct parts of the modiolus, which were best appreciated on the ''midmodiolar'' view. On this view, the medial and lateral portions of the modiolar base were

FIGURE 21-25 Absence of the barrier between the scala tympani and vestibuli in the left cochlea in a patient with congenital deafness on the left side. **A** and **B**, Axial 0.7 mm thick, T2-weighted gradient-echo images through the upper part of the right (**A**) and left (**B**) cochleas. A clear separation can be seen between the scala vestibuli/media (*small white arrow*) and scala tympani (*long white arrow*) of the second turn of the right cochlea. On the left side, only a bony separation can be seen between the apical and second turns (*double arrowhead*); there is no separation between the scala vestibuli/media and scala tympani (*white arrowheads*). The intrascalar defect was the only visible lesion in an otherwise normal-appearing cochlea on CT and MR imaging. **C** and **D**, Similar images at the level of the right (**C**) and left (**D**) modioli. The scala vestibuli/media (*small white arrows*) and tympani (*long white arrows*) can be separated from one another in the second and basal turns of the right cochlea. The modiolus has a normal appearance and can be seen as a low signal intensity structure at the base of the cochlea (*large black arrow*). The scala vestibuli/media and scala vestibuli form a single fluid-containing cavity in both the second (*white arrowheads*) and basal turns (*double arrowheads*) of the left cochlea. Moreover, the modiolus on the left side is hypoplastic (*large black arrow*) in comparison with the modiolus on the right side.

seen posteriorly within the center of the basal turn and between the basal and middle turns. The medial and lateral parts of the interscalar septum then radiated from the modiolus to the bony capsule of the cochlea anteriorly between the basal and middle cochlear turns (Fig. 21-33). Lemmerling et al. defined modiolar defects as nonvisualization of all or part of the modiolus or interscalar septum on the midmodiolar view, which was then classified as a cochlear dysplasia of the incomplete partition variety, according to Jackler et al.'s scheme (Fig. 21-34).

Other Anomalies

There is another entity that also may qualify as a partition defect and modiolar deficiency that has a known pattern of inheritance: X-linked progressive mixed hearing loss or X-linked congenital mixed deafness. This entity was originally described by Olson and Lehman in 1968 in two half-brothers.[42] In this entity, there is dilatation of the lateral part of the IAC, absence or severe hypoplasia of the bony modiolus (with a normal number of cochlear turns) and hypoplasia of the cochlear base, with or without widening of the labyrinthine segment of the facial nerve canal and dilatation of the vestibular aqueduct (Figs. 21-35 and 21-36). There is also fixation of the stapes footplate, which is not readily apparent radiographically.[43, 44] In this condition, the absence or hypoplasia of the modiolus and cochlear base is thought to result in an abnormal fistulous communication between the cerebrospinal fluid (CSF) within the IAC and the perilymphatic fluid in the scala vestibuli. This fistulous communication results in increased pressure within the cochlea and at the oval window at the stapes insertion. This increased pressure causes both a sensorineural and a conductive hearing loss and predisposes to a stapes ''gusher'' (an outpouring of fluid from the inner ear through the oval window into the middle ear cavity) at surgery for the fixed footplate.

Another cochlear anomaly not otherwise classified is scalar asymmetry within the cochlea. This anomaly has only

FIGURE 21-28 Common cavity type of cochlear-vestibular malformation. **A**, Axial 0.7 mm thick gradient-echo image through the left inner ear. Only a single fluid-filled cavity (*long white arrows*) can be seen in the right inner ear. The neurovascular bundle, however, is present in the cerebellopontine angle (*large black arrows*) and the IAC (*white arrowheads*). **B**, Axial CT image through the right inner ear. The single inner ear cavity can again be seen (*long white arrows*). The IAC (*black arrowheads*) and the tympanic segment of the facial nerve canal (*long black arrows*) can be seen. No cochlear structure is visible at the site anterior to the IAC, the site where the cochlea is normally situated (*small black arrow*).

recently been documented with high-resolution, T2-weighted MR imaging. The anterior scalar chamber contains the scala vestibuli and scala media, and the posterior scalar chamber contains the scala tympani. Normally, the anterior and posterior chambers are fairly equal in size. However, in an abnormal setting, the anterior chamber may be larger than the posterior chamber, with a ratio as high as 1.45 to 1.[26] This finding is thought to be a manifestation of cochlear dysplasia, which is often coexistent with an enlarged vestibular aqueduct. The precise relationship of the anomalies is unknown. In cases of enlargement of the anterior chamber, the scala vestibuli has been shown to be enlarged. However, the scala vestibuli contains perilymph and is *not* in direct communication with the endolymphatic system. Rather, the scala media comprises the endolymphatic cochlear duct in continuity with the remainder of the endolymphatic system including the duct and sac. Therefore, the relationship of the aqueduct and the scalar asymmetry is unclear. The scala media has not been shown to be enlarged. Future improvements in resolution may allow better definition of the structure of this anomaly.

The ''dwarf'' cochlea has been mentioned.[24] At CT the cochlea appears to be relatively normal, with a normal number of turns. However, the dimensions of the cochlea are significantly smaller than normal. The diameter of the lumen of the turns of the cochlea is also diminished. This anomaly is considered to be quite rare. The position of the facial nerve in association with this anomaly can be abnormal. The labyrinthine segment can be anteriorly positioned (see the next section).

Internal Auditory Canal and the Vestibulocochlear and Facial Nerves

The normal range of the IAC's diameter is 2 to 8 mm, with an average of 4 mm.[45] Canals smaller than 2 mm are generally considered stenotic. The IAC may also be atretic or may have a bony septum that partitions the canal into two or more separate canals.

CT may readily demonstrate either stenosis or atresia of the IAC by defining the bony margins of the canal (Fig. 21-37). On high-resolution, T2-weighted gradient echo or fast spin echo MR images, the absence of CSF between the

FIGURE 21-31 *Continued.* **D**, Gradient-echo T2-weighted parasagittal reconstructed image through the lateral part of the left internal auditory canal. On this 3DFT-CISS image the facial nerve (*large black arrow*) has a much larger diameter than the cochlear branch of the VCN (*long white arrow*). The common vestibular branch of the eighth nerve has a normal size (*small black arrows*). **E**, Gradient-echo T2-weighted parasagittal reconstructed image through the lateral part of the normal right IAC for comparison. The facial nerve (*large black arrow*) and cochlear branch of the VCN (*long white arrow*) have a similar diameter, which is a normal finding. The common vestibular branch of the VCN is normal in size (*small black arrows*). *PF*, posterior fossa; *T*, temporal lobe.

cerebellopontine angle and the intralabyrinthine fluid is a reliable sign of atresia. A thin layer of CSF may be seen in the IAC in cases of stenosis (Fig. 21-38).

The relationship of IAC stenosis/atresia to congenital sensorineural hearing loss (SNHL) is unclear. Some patients with unilateral IAC stenosis have normal hearing bilaterally, and others have hearing loss in the ear without stenosis.[46] When there is SNHL in the ear with IAC stenosis, it is unclear whether the bony deformity causes the hearing loss by compressive effects upon the vestibulocochlear nerves (VCN) or whether a membranous deformity of the cochlea or vestibule, not radiographically detectable, results in failure of neural growth induction for the VCN, with subsequent canal hypoplasia.[11, 46–48] In either case, evaluation for hypoplasia or aplasia of the VCN and/or facial nerve within the IAC may be accomplished with MR imaging.

Normally, the vestibulocochlear nerves and facial nerve can be identified when thin-section, high-resolution MR images through the IAC are obtained with any of the various techniques previously discussed. Evaluation for hypoplasia or aplasia of the nerves is best done with direct sagittal images or reconstructions perpendicular to the long axis of the IAC (Fig. 21-39) such that the nerves are visualized in cross section and an accurate assessment of their diameters can be made. In very stenotic IACs, the diagnosis may be difficult due to inability to separate the nerves.

Three types of vestibulocochlear nerve hypoplasia and aplasia can be distinguished.[49] In Type 1, the IAC is stenotic and the VCN is absent (Fig. 21-38). In cochlear implant candidates, it is important to recognize this type of aplasia because the cochlear implantation will not be successful on the side of aplasia and will not be possible when the aplasia is bilateral. In Type 2A, a common VCN is found with aplasia or hypoplasia of its cochlear branch in the presence of a labyrinthine malformation (Figs. 21-39 and 21-40). When the labyrinthine structures are normal, it is a Type 2B malformation (Fig. 21-41). Patients with Type 2 malformations often have residual hearing or only one ear is affected. Therefore, in this group, patients are not necessarily cochlear implant candidates.

Like the VCN, the facial nerve may also be congenitally hypoplastic or aplastic (Figs. 21-42 and 21-43). This anomaly may occur in isolation or as part of Moebius syndrome, also known as congenital facial diplegia, congenital oculofacial paralysis, or congenital abducens–facial paralysis. These patients not only have facial diplegia, but also bilateral lateral rectus muscle paralysis.[50] In patients with isolated congenital facial nerve palsy, the VCN and cochlea are usually normal. However, in Types 1, 2A, and 2B malformations of the VCN, an abnormal course of the facial nerve frequently can be found. The nerve can leave the IAC in its middle third and then continue in a separate facial nerve canal (Fig. 21-44). The nerve can also be situated in a completely separate canal parallel to the IAC (Figs. 21-45 and 21-46). Finally, the nerve can also pass between the temporal bone and temporal lobe.

Duplication of the facial nerve, also referred to as a bifid facial nerve, is another anomaly that, although usually associated with other congenital anomalies, can occur in isolation. Most commonly, the facial nerve will bifurcate along the proximal aspect of the tympanic segment inferior to the lateral semicircular canal into a larger lateral branch and a smaller medial branch. These two branches usually reunite at the stylomastoid foramen (Fig. 21-47). Rarely, the facial nerve may bifurcate proximal to the geniculate

ganglion (Fig. 21-48). In this variation, there may also be duplication of the IAC.[51]

Anterior migration of the facial nerve has been described with certain cochlear malformations.[52] It has been proposed that because of the intimate relationship between the development of the cochlea and the facial nerve, cochlear development or lack thereof may influence the position of the proximal or labyrinthine segment of the facial nerve canal. In some types of malformations, such as cochlear hypoplasia, common cavity malformations, and ''dwarf'' cochlea, lack of a significant cochlear mass results in anterior migration of the proximal or labyrinthine segment of the facial nerve as it attempts to take a more direct course to the pterygopalatine fossa and ganglion (Figs. 21-49 and 21-50). The nerve can exit the IAC more medially closer to the porus.

The tympanic and mastoid segments of the facial nerve can also be in an abnormal position. This is most commonly seen in association with EAC and ossicular abnormalities. This has been described in the section on middle ear anomalies. However, facial nerve abnormalities can be found in isolation. The tympanic segment of the facial canal

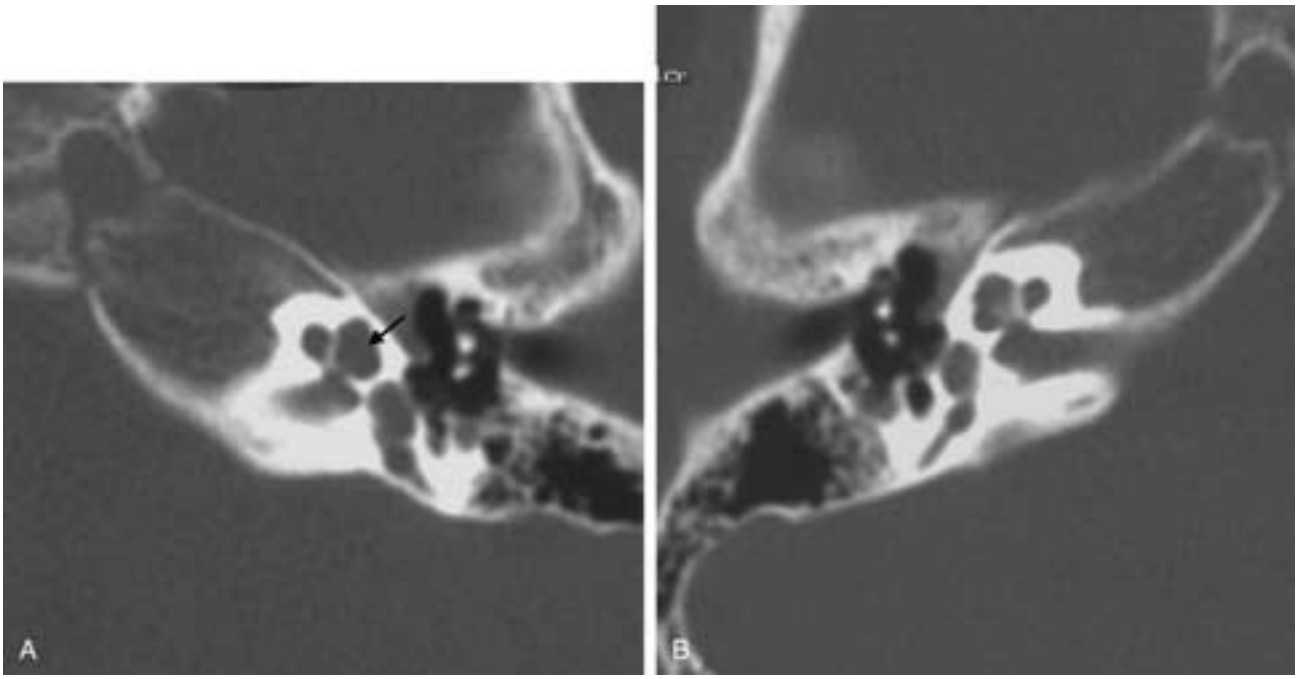
Copyright © 2003, Mosby, Inc. All rights reserved.

can be dehiscent, with the nerve bulging into the middle ear. The facial nerve can migrate inferiorly to abut the stapes or cross the promontory. Identification of the position of the facial nerve is always a crucial part of preoperative planning.

Vestibular Aqueduct

Valvassori and Clemis were the first to report an association between SNHL and a dilated vestibular aqueduct, as identified on polytomograms in 1978.[53] In their study of 3700 consecutive patients, 50 (1.4%) showed an enlarged vestibular aqueduct (more than 1.5 mm in diameter). Of the 50 patients, 60% had radiographically identifiable anomalies of the vestibule, semicircular canals, and cochlea. The malformed cochleas were classified into the Mondini or Mondini-Alexander types. However, only 8 of the 50 patients (16%) had identifiable cochlear anomalies on polytomography. This association of vestibular aqueductal dilatation and incomplete partitioning of the cochlea (classic Mondini's deformity) was thought to be likely given the embryology of these structures. The vestibular aqueduct and partitioning of the cochlea were known to be the last-developing entities of the inner ear, and a teratogen exerting its effects in this late stage of development might easily interfere with the normal development of both of these structures simultaneously. The remaining 40% of the patients showed no other identifiable anomalies of the inner ear and may have had associated pathology of the membranous labyrinth, which was not visible with polytomography. The authors coined the term *large vestibular aqueduct syndrome*, implying that this anomaly could exist in isolation. The clinical findings in these patients with enlargement of the vestibular aqueduct included vestibular symptoms in five patients. The remaining 45 patients demonstrated either pure SNHL or mixed hearing loss.

Since Valvassori and Clemis's original polytomographic study, there have been many studies using both CT and MR imaging for the evaluation of the large vestibular aqueduct syndrome.[53–58] On CT, the bony confines of the enlarged aqueduct can easily be demonstrated. The vestibular aqueduct is considered enlarged if it is more than 1.5 mm and is therefore larger than the normal posterior semicircular canal, which runs anterior and parallel to the aqueduct. On T2-weighted gradient echo or fast spin echo MR imaging, the fluid-filled endolymphatic duct and the sac within the bony vestibular aqueduct are hyperintense and surrounded by hypointense bony structures (Figs. 21-19, 21-36, 21-51 to 21-53). Multiplanar imaging and 3D reconstructions provide further detail of the enlarged endolymphatic duct and sac (Figs. 21-51 and 21-53). Also, the 3DFT gradient echo images and other T2-weighted sequences show the full extension of the endolymphatic sac into the posterior fossa (often invisible on CT). This extraosseous sac is a major component of the enlarged endolymphatic structure (Fig. 21-51). Usually the endolymph is slightly more hyperintense than CSF because of differing flow and pulsation rates. The MR images may show a thin dural lining between the endolymphatic sac and CSF, which makes it possible to follow the endolymphatic sac from the vestibule into the posterior fossa (Figs. 21-51 to 21-53). Sometimes on MR imaging, a portion of the endolymphatic duct and sac has a lower signal intensity than CSF or intralabyrinthine fluid. This is seen most frequently at the posterior edge of the sac, near the sigmoid sinus, but is occasionally seen in the entire endolymphatic duct and sac



VIEW IMAGE

(Fig. 21-53).[59] This low signal may represent fibrous tissue. Endoymph is not the only component of the normal endolymphatic sac and duct. Histologically, these structures also contain rugosity, loose vascular subepithelial connective tissue and cuboidal or columnar epithelial cells, and it may be that the low signal intensity corresponds to these rugose portions.[60]

Many of the older studies using polytomography or older CT scanners with thicker sections implied that enlargement of the vestibular aqueduct frequently exists without a cochlear anomaly. More recent studies using either high-resolution CT or MR imaging have shown vestibular aqueduct enlargement or a large endolymphatic duct and sac (LEDS) to coexist frequently with cochlear anomalies.[61] In a study by Lemmerling et al. in 1997 using high-resolution CT,[41] modiolar deficiencies of the cochlea were detected in all patients with enlarged vestibular aqueducts. Another study using high-resolution, fast spin echo, T2-weighted MR imaging showed 76% of patients with LEDS to have cochlear anomalies including modiolar deficiency (94%), gross dysmorphism (71%), and scalar asymmetry (65%).[26] Another study using MR imaging measured the modiolus in normal subjects and in patients with LEDS and found a high association between a smaller than normal modiolus and LEDS, but also found cases of LEDS with a normal modiolus.[62]

Most patients with enlarged vestibular aqueducts have progressive SNHL that begins in infancy and childhood. The mechanism by which hearing loss is induced is still unknown. Various theories have been proposed. Transmission of hyperosmolar proteins in the enlarged endolymph sac through the enlarged endolymphatic duct and eventually into the cochlear duct (scala media) may cause damage to the neuroepithelium.[56, 61] In patients with a modiolar deficiency, elevations in CSF pressure associated with certain activites [56, 57] may be transmitted into the cochlea via

Copyright © 2003, Mosby, Inc. All rights reserved.

a relatively incompetent lateral wall of the IAC, potentially injuring the membranous labyrinth and hair cells within the organ of Corti.[41] Some of these theories have originated from studies showing either greater SNHL with greater degrees of endolymphatic duct enlargement[56, 61] or greater SNHL with more extensive modiolar deficiencies.[41] However, others have shown no positive correlation between the degree of SNHL and the degree of endolymphatic duct enlargement or modiolar abnormalities.[63]

VASCULAR ANOMALIES

Internal Carotid and Stapedial Arteries

Partial Absence and Aberrant (Lateral) Course

An aberrant course of the internal carotid artery (ICA) through the middle ear is rare, with approximately 45 cases reported in the English language literature. Most of these cases occurred in females, with the majority occurring on the right side.[64, 65] No convincing explanation for the female or the right-sided predominance has been presented.

Absence of the normal vertical petrous portion of the ICA leads to the development of an aberrant or lateral-coursing carotid artery. The vertical petrous portion is replaced by the more lateral-coursing and enlarged inferior tympanic and caroticotympanic arteries. These arteries normally form part of the tympanic arterial plexus. The inferior tympanic artery normally originates from the ascending pharyngeal artery and extends through the inferior tympanic canaliculus into the middle ear. The caroticotympanic artery normally originates from the vertical petrous segment of the ICA and extends into the middle ear (Fig. 21-54A). When the vertical petrous segment of the ICA is absent, the inferior tympanic artery enlarges and forms the proximal portion of the ICA, which anastomoses more distally through an enlarged inferior tympanic canaliculus with an enlarged caroticotympanic artery (Fig. 21-54A). The caroticotympanic artery carries blood flow to the transverse petrous segment of the carotid artery. The flow through the enlarged caroticotym-

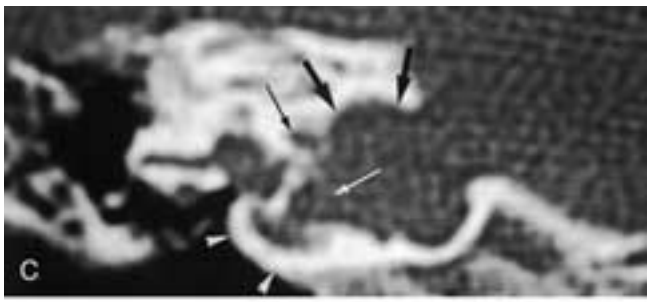

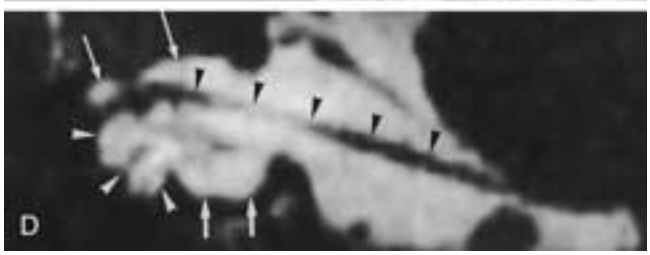

FIGURE 21-36 X-linked deafness/gusher ear in a patient with congenital deafness. **A**, Axial CT image through the right inner ear. There is no bony barrier between the IAC canal and the basal turn of the cochlea (*long white arrow*), and the modiolus is absent. There is a bulbous enlargement of the IAC (*large black arrows*), which is another typical finding in patients with X-linked deafness. The diameter of the vestibular aqueduct (*small black arrow*) is larger than the diameter of the posterior semicircular canal (*black arrowheads*). Therefore, a large vestibular aqueduct is present. **B**, Axial T2-weighted gradient-echo image through the right inner ear. The bulbous IAC can again be seen (*long white arrows*). The bony separation between the fluid inside the IAC and the basal turn of the cochlea is absent (*long black arrow*), as is the modiolus. Therefore, the cochlear branch of the VCN can be followed from the IAC into the cochlea, and even the separation in some of the distal branches (spiral ganglia) can be seen (*black arrowheads*). The enlarged endolymphatic duct (*small white arrow*) can be recognized and has a larger diameter than the posterior semicircular duct (*white arrowhead*). Normal facial nerve (*small black arrow*) and VCN (*large black arrow*) in the right cerebellopontine angle. Vestibule (*V*). **C**, Coronal CT image through the right inner ear. The bulbous enlargement of the right IAC can again be seen (*large black arrows*), and the fluid inside the IAC continues, without any barrier (*long white arrow*), into the cochlea (*white arrowheads*). The labyrinthine segment of the facial nerve canal is enlarged (*long black arrow*). **D**, Coronal T2-weighted gradient-echo image through the right inner ear. The IAC is wide and has a bulbous shape (*small white arrows*), and the CSF in the IAC cannot be separated from the fluid inside the cochlea (*white arrowheads*). The facial nerve can be followed in the cerebellopontine angle and IAC (*black arrowheads*) and continues in the enlarged labyrinthine segment of the facial nerve canal. Normally, this segment of the facial nerve canal is very small, and there is no space left between the nerve and the walls of the canal. However, in gusher ears the canal enlarges, and fluid can be found between the nerve and the canal walls (*long white arrows*).

The facial nerve (*long white arrows*) can be seen inside the lateral part of the IAC and disappears in the facial nerve canal. The common vestibular branch (*long black arrows*) and cochlear branch (*large black arrows*) of the VCN can be followed in the IAC, and branches (spiral ganglia) of the latter nerve can be followed inside the cochlea (*white arrowheads*). One can look inside the abnormal cochlea, as no bony barrier exists between the IAC and the lumen of the cochlea. Defect in the base of the cochlea (*black arrowheads*).

FIGURE 21-38 Type 1 malformation, aplasia of the VCN with a stenotic IAC in a patient presenting with complete congenital deafness. **A**, Axial 0.7 mm thick T2-weighted gradient-echo image through the left inner ear. A very narrow fluid-filled IAC can be seen (*long white arrows*). On the axial images only a single nerve, the facial nerve, can be found in the left cerebellopontine angle (*large black arrows*). Normal fluid in the common crus (*white arrowheads*). **B** and **C**, Parasagittal T2-weighted gradient-echo images perpendicular to the course of the nerves at the level of the left cerebellopontine angle (**B**) and IAC (**C**). **B**, In the cerebellopontine angle, only the facial nerve (*large black arrow*) can be seen anterosuperior to the floccule (*F*). **C**, Only a little CSF can be visualized inside the very narrow IAC (*large black arrow*). Nerves are difficult to visualize in such a narrow IAC. Here the facial nerve can be depicted lying against the posteroinferior wall of the IAC (*long white arrow*). The VCN is absent. *C*, Cerebellum; *T*, temporal lobe.

panic segment is reversed from the normal direction, carrying blood back into the ICA rather than away from it into the middle ear region.

A persistent stapedial artery (PSA) is often found in association with an aberrant ICA. The PSA leaves the aberrant ICA through a small canaliculus to enter the middle ear cavity, where it courses along the cochlear promontory. It then passes through the crura of the stapes and either enters the canal for the tympanic portion of the facial nerve or runs parallel to it in a separate canal. The PSA continues superiorly to supply the middle meningeal artery through enlargement of the superior tympanic or superficial petrosal artery. The foramen spinosum, through which the middle meningeal artery normally travels after originating from the internal maxillary artery, is absent. The PSA may also occur without an aberrant ICA. In this situation, the vertical petrous segment of the ICA is present and the PSA is formed by enlargement of the more distal caroticotympanic artery arising from the vertical petrous ICA (Figs. 21-54B, 21-55 and 21-56).[66, 67]

There is no universally accepted etiology for the aberrant carotid artery.[68] Among the proposed mechanisms is a congenital failure of ossification of the bony limiting wall of the petrous carotid canal. Some authors have reported that the bony plate is frequently less than 0.5 mm thick, and with age, as the vessel elongates and becomes tortuous, it may protrude through the defect into the tympanic cavity.[64, 69] Persistence of embryonic vessels also may produce sufficient traction to pull the artery into the middle ear.[64]

Signs and symptoms of an aberrant ICA include tinnitus, hearing loss (mostly conductive), a red-blue pulsatile mass behind the tympanic membrane, vertigo, and a sensation of fullness in the ear.[64, 69] In some cases, otalgia has been reported as one of the initial symptoms. The tinnitus may be caused either by the direct mechanical transmission of the vessel's pulsations to the tympanic membrane and ossicles or by the audible sound produced by arterial blood flow emanating from the abnormal vessel within the middle ear. Pulsatile tinnitus has also been reported to occur with erosion of the bone separating the aberrant ICA and basal turn of the cochlea, allowing direct transmission of pulse vibration to the cochlea. As well, in this scenario, although the aberrant ICA is a congenital vascular malformation, the tinnitus may not occur until the erosion of the bone separating the vessel from the cochlea occurs.[70] Hearing loss may result from dampening of the tympanic membrane vibrations or from encroachment or erosion of the ossicles.[64] Still, many patients are asymptomatic.

Not infrequently, the red-blue mass behind the tympanic membrane has been inadvertently ruptured during therapeutic myringotomies, biopsy for suspected glomus tumors, or both. This has resulted in catastrophic hemorrhage from the middle ear, emergently treated by ear packing.

CT of an aberrant ICA shows an enhancing soft-tissue mass in the hypotympanum extending toward the oval window area, indenting the promontory and displacing the tympanic membrane laterally (Fig. 21-57).[64] The aberrant ICA may be detectable on MR imaging with flow-sensitive techniques, MR angiography (MRA) or fast spin echo, T-2 weighted images as a laterally positioned vascular structure (Fig. 21-57). Grooving of the apical, middle, and basilar turns of the cochlea by the artery also may be seen on CT.[68] The lateral bony wall of the carotid canal is dehiscent, a finding best appreciated on CT. If there is an associated PSA, the foramen spinosum is absent and there is enlargement of the anterior tympanic facial nerve canal or a canal parallel to it.

Asymptomatic aberrant arteries require no treatment. Therapy usually is reserved for patients with pulsatile tinnitus, hemorrhage, or cranial nerve palsies. Intervention includes the interposition of synthetic material between the artery and ossicles, disarticulation of the ossicular chain, or ligation of the ICA in cases of hemorrhage.[64]

Agenesis

The etiology of congenital absence of the ICA is unknown. Keen has suggested that unilateral absence of the ICA may result from mechanical stresses in early development such as pressure effects, excessive bending of the

Copyright © 2003, Mosby, Inc. All rights reserved.

cephalic end of the embryo from side to side, or the effects of amniotic adhesions.[71] No explanation has been offered for bilateral absence of the ICA, which is extremely rare.

Symptoms may or may not lead to the discovery of an absent ICA. The agenesis may be discovered as an incidental finding during workup for an unrelated problem[72] or, more commonly, during the workup for neurologic symptoms. In 42 reported cases of congenital absence of the ICA, 12 patients initially had subarachnoid hemorrhage caused by a ruptured intracranial aneurysm. Other clinical presentations include multiple cranial nerve palsies caused by compression by a dilated loop of the basilar artery, hemiparesis after minor head trauma, and various other neurologic signs and symptoms resulting from major head injuries.

CT usually shows unilateral absence of the carotid canal in the petrous part of the temporal bone or a small vertical cleft, possibly representing an abortive carotid canal (Fig. 21-58). Internal carotid angiography demonstrates unilateral absence of the ICA. Angiography also shows the frequent occurrence of associated anomalies of the remaining vasculature (i.e., dilated basilar artery collaterals, ipsilateral dilation of the posterior communicating artery filling the

FIGURE 21-39 Common cavity-type cochlear-vestibular malformation with associated aplasia of the cochlear branch of the VCN, Type 2A malformation. **A**, Axial 0.7 mm thick gradient-echo image through the left inner ear. A fluid-filled cavity (*white arrowheads*) is seen posterior and lateral to the fundus of the IAC. No fluid can be seen at the site where the cochlea is expected to be located (*large white arrows*). A normal posterior semicircular duct can be recognized (*long white arrow*). Only two nerves are seen passing through the IAC—the facial nerve (*small black arrow*) and a common VCN or vestibular nerve (*small white arrow*). **B**, Axial CT image through the left inner ear. Confirmation of the absence of a separate cochlear structure (*black arrows*) and the presence of a common cavity (*black arrowheads*) and normal posterior semicircular canal (*long black arrow*). **C**, Gradient-echo images, oblique sagittal reconstructions of the left inner ear at the level of the cerebellopontine angle (*1*), and porus (*2*) and fundus (*3*) of the IAC; see the levels on **A**. A smaller facial nerve (*long black arrows*) and a thicker common, or rudimentary, VCN (*small black arrows*) can be followed from the cerebellopontine angle (*1*) to the fundus of the IAC (*3*). A separate cochlear branch normally situated in the anterior and inferior parts of the IAC cannot be recognized, and there is no bifurcation into a superior and inferior vestibular branch. **D**, Gradient-echo images, oblique sagittal reconstructions of a normal inner ear for comparison. The facial nerve again can be depicted as a smaller nerve (*long black arrows*). The common VCN (*small black arrows*) gives off its cochlear branch (*long white arrows*) when it reaches the porus (*2*) and divides into a superior (*black arrowhead*) and inferior (*white arrowhead*) vestibular branch deeper in the IAC (*3*). *PF*, posterior fossa; *T*, temporal lobe. A cochlear implant was installed, and the results were moderate to satisfactory. This case proves that cochlear implantation can be of benefit once a fluid-filled inner ear cavity is found and the presence of a nerve, which is not the facial nerve, can be demonstrated.

corresponding anterior or middle cerebral arteries or both, ipsilateral ophthalmic or anterior cerebral arteries arising from the middle cerebral artery, or aneursyms). Congenital absence of both ICAs has also been reported. Their absence was compensated for by a hypertrophied accessory meningeal artery through an enlarged foramen ovale on one side and a trigeminal artery on the other.[73] Spin-echo T1- and T2-weighted MR images show absence of the normal ICA flow void at the skull base, and MRA shows lack of flow-related enhancement.[72]

FIGURE 21-40 Type 2A malformation, aplasia of the cochlear branch of the VCN in the presence of an abnormal membranous labyrinth. **A** and **B**, Axial 0.7 mm thick gradient-echo T2-weighted images through the left inner ear at the level of the IAC (**A**) and below the level of the IAC (**B**). **A**, Fluid can be seen in an abnormal vestibule (*double arrowhead*) and in an enlarged posterior semicircular duct (*small white arrow*). The facial nerve (*white arrowheads*) and a common undividing VCN (*long white arrows*) can be followed to the fundus of the IAC and the region of the abnormal inner ear. **B**, The abnormal shape and enlargement of the vestibule (*double arrowhead*) are depicted on this image. The shape of the posterior semicircular duct is abnormal (*small white arrow*). **C** and **D**, Parasagittal 3DFT-CISS reconstruction perpendicular to the nerves at the level of the cerebellopontine angle (**C**) and IAC (**D**). **C**, Both the facial nerve (*black arrowhead*) and the VCN (*long white arrow*) can be seen in the CSF of the cerebellopontine angle. **D**, The facial nerve can be seen in its normal position anterior and high in the IAC (*white arrowhead*). The VCN, however, is not dividing into cochlear and vestibular branches and can be followed as a single nerve to the fundus of the IAC (*long white arrow*). *C*, Cerebellum; *T*, temporal lobe.

Jugular Vein

High Jugular Bulb

Protruding/Dehiscent Jugular Bulb

The dome of the jugular bulb normally lies beneath the floor of the tympanic cavity. When it is higher, it is referred to as a high jugular bulb. Various definitions of a high jugular bulb are found in the literature. Anatomic studies have defined it as lying above the level of the inferior tympanic rim or bony annulus of the temporal bone, as well as a bulb that abuts the round window or lies less than 2 mm under the inferior edge of the internal acoustic meatus. Some CT studies have defined a high bulb as one that lies at the level of the basal turn of the cochlea (Figs. 21-59 and 21-60).[74–76] Because of its high position, the bony covering of the jugular bulb may be thin or *dehiscent*, rendering the bulb vulnerable to trauma (Fig. 21-61). A high jugular bulb has been reported in up to 6% of temporal bones examined histologically, making it the most common vascular anomaly of the petrous portion of the temporal bone.[75] The anomaly is more common on the right side, as the dural sinuses and jugular vein are larger on the right in 75% of individuals.[77]

This entity bears some relation to the degree of pneumatization of the mastoid air cells. In poorly pneumatized mastoid air cells, the sigmoid sinus is more anterior, the jugular fossa tends to be deep, and the jugular bulb has a correspondingly high dome.[78] The height of the bulb is significant because of the risk of inadvertently entering the vein during myringotomy or middle ear procedures. The high position of the bulb can be appreciated on both CT and MR imaging. The thin or dehiscent hypotympanic bony wall can be appreciated with CT (Figs. 21-59 to 21-61).

The high jugular bulb is usually an incidental finding on clinical examination. It is seen as a bluish discoloration in the posteroinferior quadrant of the tympanic membrane and on radiographic examination.[79] However, conductive hearing loss, pulsatile tinnitus, and Meniere's disease have all been reported to occur with this vascular anomaly.[74, 77] Conductive hearing loss and pulsatile tinnitus have been attributed to a high *lateral* jugular bulb and to one of three mechanisms: obstruction of the round window niche, contact with the tympanic membrane, or ossicular chain interference. The first two mechanisms are considered more common than ossicular chain interference, which requires an extremely high jugular bulb reaching as far as the incudostapedial joint.[77] A high *medial* jugular bulb has been proposed to induce Meniere's disease by contacting and compressing the distal portion of the vestibular aqueduct and endolymphatic duct and/or sac. The compression of the endolymphatic duct and/or sac could result in a decrease in endolymph resorption or disruption of the venous drainage of the duct and/or sac, and thereby inducing Meniere's disease.[74] Surgical lowering of a high medial jugular bulb has been proposed as a treatment option in symptomatic patients and has shown some efficacy.[74]

Jugular Diverticulum

A jugular diverticulum (JD) is a smooth outpouching of the jugular bulb that extends superiorly, medially, and

FIGURE 21-41 Type 2B malformation, hypoplasia of the cochlear branch of the right VCN in the presence of a normal labyrinth in a patient with severe but not complete congenital deafness on the right side. **A** and **B**, Axial T2-weighted gradient-echo images through the right (**A**) and left (**B**) IACs. **A**, A normal cochlea with distinguishable scala vestibuli/media and scala tympani can be seen (*small white arrows*). A normal-sized inferior vestibular branch (*white arrowheads*) can be seen, but the cochlear branch (*long white arrow*) of the VCN is hypoplastic. **B**, On the left side, both the cochlear (*long white arrows*) and inferior vestibular branches (*white arrowheads*) are normal in size. The scala vestibuli/media and scala tympani can again be distinguished in a normal-appearing cochlea (*small white arrows*). **C** to **F**, Parasagittal 3DFT-CISS reconstruction through the right (**C**) and left (**D**) cerebellopontine angles and through the right (**E**) and left (**F**) fundi of the IAC. **C**, The sizes of the facial nerve (*long black arrow*) and the VCN (*large black arrow*) are similar. Normally the VCN is one and a half to two times larger in diameter. The small diameter of the VCN corresponds with a smaller number of neuronal fibers in the ''hypoplastic'' nerve. **D**, On the normal left side, the VCN (*large black arrow*) is at least twice as large as the facial nerve (*long black arrow*). **E**, A hardly visible cochlear branch (*long white arrow*) and common undividing vestibular branch (*small white arrow*) of the VCN can be seen. The VCN therefore is hypoplastic. The facial nerve has a normal size (*black arrowhead*). **F**, On the left side, a normal facial nerve (*white arrowhead*) and a normal-sized cochlear branch (*long white arrow*) and dividing common vestibular branch (*small white arrow*) of the VCN can be seen. *C*, Cerebellum.

posteriorly in the temporal bone. This venous anomaly is thought to be rare, with only 21 cases reported in the English language literature. However, the apparent rarity may, in part, be due to the fact that many patients with this entity are asymptomatic.[80–82] There are characteristic differences between a JD and a protruding (high) jugular bulb. A JD is situated more medially and posteriorly in the petrous bone than is a high jugular bulb. A JD does not protrude into the middle ear, is not visible on inspection, and is not exposed to surgical trauma from a myringotomy or tympanotomy. The diagnosis of a JD is made only radiographically. A high jugular bulb can be diagnosed by both radiologic and otoscopic examinations.[78] In addition, a JD, unlike a high or protruding jugular bulb, is more common on the left side and has been reported to be more common in women.[80, 82]

Symptoms produced by a JD are controversial but would presumably be related to its size and extent. The structures with which a JD may come in contact with include the cochlear aqueduct, vestibular aqueduct/endolymphatic duct and/or sac, the posterior semicircular canal (PSCC), and the IAC. Hearing loss from a JD has been described as sensorineural and may theoretically result from encroachment on either the IAC or the PSCC. Tinnitus has been proposed to be the result of turbulent blood flow within the JD. Vertigo, SNHL, tinnitus, and aural fullness, mimicking Meniere's disease, could result from compression of the endolymphatic duct and/or sac (Fig. 21-62).[82]

CT demonstrates the JD in continuity with the jugular bulb, extending superiorly into the petrous pyramid (Fig. 21-62). The bony margins are smooth, consistent with slow remodeling without evidence of permeative destruction. The JD may encroach upon the IAC, the vestibular aqueduct, or the PSCC.[81] The most superior extension of the JD lies in a plane higher than the level of a protruding jugular bulb, often reaching the cranial margin of the petrous pyramid. Documentation of a JD with MR imaging may not be as straightforward as with CT. Contrast-enhanced, T1-weighted images may highlight the jugular bulb and JD if there is slow enough flow. MR venography, utilizing either 2D time-of-flight or phase contrast techniques may also demonstrate the JD.

Agenesis and Stenosis

Agenesis of the jugular bulb and sigmoid sinus is extremely rare. In these cases, the absent sigmoid sinus redirects the flow from the transverse sinus into a canal posterior and superior to the petrous pyramid. This canal then drains directly through transmastoidian venous channels into adjacent scalp veins. CT and MR imaging of the temporal bone and skull base will document the absent sigmoid sinus and jugular bulb, along with the aberrant venous drainage system. Aberrant venous drainage may also result from congenital stenosis of the jugular foramen, in which the jugular vein is present but small (Fig. 21-63).[83]

MALFORMATIONS OF THE PETROUS BONE ASSOCIATED WITH MENINGITIS

CSF leakage via the temporal bone structures is a rare but potentially life-threatening condition. Most CSF fistulas of the temporal bone are acquired and are a result of either

Copyright © 2003, Mosby, Inc. All rights reserved.

trauma or infection. Congenital abnormalities of the temporal bone are a much rarer cause of CSF fistulas and should always be suspected in cases of recurrent meningitis in the absence of an inciting event. Congenital CSF fistulas of the temporal bone have been traditionally classified as perilabyrinthine or translabyrinthine (Figs. 21-64A,B).[84] Perilabyrinthine fistulas are rare and occur through defects close to but not involving the labyrinth. Translabyrinthine fistulas, which are far more common, are usually associated with anacusis, severe labyrinthine dysplasia, and a route via the IAC.

Both the translabyrinthine and perilabyrinthine fistulas tend to present in the first 5 to 10 years of life. The various presentations include CSF rhinorrhea with an intact tympanic membrane as CSF passes from the middle ear down into the eustachian tube, nasopharynx, and nasal cavity, resulting in nasal discharge; CSF otorrhea in a child with a perforated tympanic membrane or with a myringotomy tube for presumed serous otitis media; or recurrent meningitis.

Perilabyrinthine Fistulas

Several different routes for the development of perilymphatic fistulas have been proposed, and some have been confirmed pathologically (Fig. 21-64A).

Dehiscence of the Tegmen Tympani

A CSF fistula may arise from congenital absence of a portion of the tegmen tympani.[85–87] The tegmen tympani is normally formed by the joining of the superior aspect of the petrous part of the temoral bone with the caudal squamous portion of the temporal bone.[88, 89] Fusion of the petrosquamosal suture is usually complete by 1 year of age but can be delayed by growth abnormalities. Small bony dehiscences have been reported to occur in up to 34% of the population, although actual meningoceles, meningoencephaloceles, and fistulas are rare. This is likely secondary to the fact that dural weakening, which is not as common as bony dehiscence, is necessary for such communication.[90–92] CSF fistulas through a dehiscence in the tegmen tympani usually present
